CONTENTS

OF

VOL. LX

OF

THE INDIAN MEDICAL GAZETTE

	<i>Page</i>
ORIGINAL ARTICLES:—	
The Problem of Epidemic Dropsy and Beriberi. By Major Hugh W. Acton, I.M.S., and Major R. N. Chopra, M.A., M.D. (Cantab.), I.M.S. . . .	1
Stone in the Bladder. By Lieut.-Col. Henry Smith, C.I.E., (Retd.), I.M.S. . . .	18
Serum Reactions in Syphilis. By Major R. B. Lloyd, M.A., M.B., B.C., I.M.S. . . .	19
A Preliminary Note on the Successful Treatment of Kala-azar with "Stibamine Glucoside." By L. E. Napier, M.R.C.S., L.R.C.P. . . .	24
Typhus-Like Fever, Probably Tick-Typhus, in Central India. By Lieut.-Col. J. W. D. Megaw, I.M.S., Major F. B. Shettle, I.M.S. and Dharendra Nath Roy, M.B. (Cal.), D.T.M. (Cal.) . . .	53
Indian Tick-Typhus. By Lieut.-Col. J. W. D. Megaw, I.M.S. . . .	58
Notes on Carbon Tetrachloride as an Anthelmintic. By Asa C. Chandler, Ph.D., and A. K. Mukerji, M.B. . . .	61
Gaucher's Type of Splenomegaly, in a Mahratta Village, with a Case Treated by Splenectomy. By Capt. W. C. Spackman, M.B., B.S. (Lond.), M.R.C.S., L.R.C.P., I.M.S., with Pathological Notes by Lieut.-Col. F. P. Mackie, O.B.E., M.D., M.Sc., F.R.C.P., F.R.C.S., I.M.S. . . .	69
Variations in the Potency of Digitalis Preparations in the Tropics. By R. N. Chopra, M.A., M.D. (Cantab.), Major, I.M.S., S. C. Bose, M.B. (Cal.), M.R.C.P., D.T.M. (Lond.), and P. De, M.B. (Cal.), Capt., late I.M.S. . . .	93
An Investigation into the Origin of Cholera Epidemics in the Jharia Coal-fields. By G. C. Maitra, Capt., I.M.S. . . .	97
The Treatment of Asthma. By Hugh W. Acton, Major, I.M.S., and R. N. Chopra, M.A., M.D. (Cantab.), Major, I.M.S. . . .	101
The Migration of Hookworm Larvæ in Soil. By Asa C. Chandler, Ph.D. . . .	105
The Cure of Schistosomiasis by the Intravenous Injection of Antimony Tartrate. By Dr. J. B. Christopherson, C.B.E., M.A., M.D. (Cantab.), F.R.C.P., F.R.S. (Eng.) . . .	108
The Treatment of Stiff Joints. By H. Hallilay, M.B., Lieut.-Col., I.M.S. . . .	111
Detaining of Patients. By C. C. Murison, F.R.C.S.E., D.P.H., D.T.M., etc., Lieut.-Col. I.M.S. . . .	113
Left-Handedness. By Prakash Chandra Das, M.B. . . .	116

ORIGINAL ARTICLES—(Continued)

Page

Combined Carbon Tetrachloride and Oil of Chenopodium in the Treatment of Hookworm Disease. By Asa C. Chandler, Ph.D., and A. K. Mukerji, M.B.	145
Clinical Studies on Digitalis in Bengal. By S. C. Bose, M.B., M.R.C.P., D.T.M. (Lond.)	147
The Treatment of Cholera by Cresol and Acid. By Lieut.-Col. F. J. Palmer, R.A.M.C. (Retd.)	155
A Note on the Outdoor Organisation of the Asansol Mines Board of Health. By Dr. J. W. Tomb, O.B.E., M.D., D.P.H.	156
Is <i>Trichomonas Hominis</i> Pathogenic? By Capt. P. Ganguli, B.A., D.T.M. (Bengal)	160
Trichomonas Infection in the Urine. By Assistant Surgeon S. K. Ghosh Dastidar, M.B., D.T.M. (Bengal)	160
On the Technique and Significance of the Rosindole Reaction, applied to Urine. By A. Neave Kingsbury, M.B., B.S. (Lond.), D.P.H., D.T.M. & H., and K. Kanagarayer, L.M.S. (S'pore)	161
Intravenous Injections of Sodium Iodide in the Treatment of Goitre. By Lieut. E. A. Davis, I.M.D., and P. Bell, I.M.D.	163
Giant Urticaria. By Hugh W. Acton, Major, I.M.S.	197
Observations on the Anti-Diabetic Properties of <i>Cephalandra Indica</i> , (<i>Telakucha</i>). By R. N. Chopra, M.A., M.D., B.Ch. (Cantab.), Major, I.M.S., and J. P. Bose, M.B. (Cal.), F.C.S. (Lond.)	201
Recent Advances in the Operative Treatment of Intestinal Stasis. By H. Hallilay, Lieut.-Col., I.M.S.	202
The Value of the Aldehyde Test in the Diagnosis of Kala-Azar. By Capt. P. Ganguli, B.A., D.T.M. (Bengal)	204
Observations on the Treatment of Kala-Azar with Urea Stibamine in the Medical Out-patient Department of the Medical College Hospital, Calcutta. By N. C. Kapur, M.R.C.S. (Eng.), L.R.C.P. (Lond.), Major, I.M.S.	206
Intravenous Anæsthesia in Surgical Practice. By J. P. Arland, (T.C.), Lieut., I.M.S.	210
Quinine Plus Alkalies in the Treatment of Malaria. By K. V. Raju	212
Choroidal Hæmorrhage Following Cataract Extraction. By M. M. Cruickshank, B.Sc., M.B., Ch.B., Capt., I.M.S.	213
Abdominal Tuberculosis in Indian Practice. By Lieut.-Col. E. W. C. Bradfield, M.S., F.R.C.S., I.M.S.	249
Sub-Periosteal Excision of Joints. By Lieut.-Col. H. Hallilay, I.M.S.	252
A Note on the Disinfestation of Houses by Fumigation with Cresol. By R. B. Lal, M.B., B.S., D.P.H., D.T.M. & H., and C. D. Tiwari, M.D., B.S., D.P.H.	255
Yaws (Frambæsia) in the Chin Hills. By P. Bell, I.M.D.	259
Report on a visit to the Leper Island of Culion and on the Anti-Leprosy Work in the Philippine Islands. By Dr. E. Muir, M.B., Ch.B., M.D., F.R.C.S.	261
Carrel's Treatment and Electrolytic Chlorine as an Antiseptic. By Dr. Ernest F. Neve, M.D., F.R.C.S. (Ed.)	264
Treatment of Varicose Veins of the Leg by an Occlusion Method. By Capt. D. R. Kehar, I.M.S. (T.C.)	265
Diabetes and Insulin Treatment in Bengal. By Lal Mohan Ghosal, L.M.S.	266
Cholera in Bengal: Past and Present. By Lieut.-Col. A. B. Fry, C.I.E., D.S.O., M.D. (Lond.), D.P.H., I.M.S.	301

ORIGINAL ARTICLES—(Continued)

Preliminary Observations on Acquired Diseases of the Heart and Aorta as met with in Bengal. By Uma Prasanna Basu, M.B., M.R.C.P. (Ire.)	307
A Note on the Efficacy of <i>Neem-battis</i> in the Destruction of Rats and Rat Fleas in Rat Burrows. By C. D. Tiwari, M.B., B.S., D.P.H., and R. B. Lal, M.B., B.S., D.P.H., D.T.M. & H.	310
Certain Aspects of Litholapaxy. By Lieut.-Col. R. W. Anthony, M.B., C.M., F.R.C.S.E., I.M.S.	311
Cellulitis of the Orbit. By Major R. E. Wright, I.M.S., and C. G. Taylor, I.M.D.	312
The Art of the Indian Chiropodist. By R. L. Spittel, F.R.C.S.E. (Eng.)	316
Canine Leishmaniasis in Bombay. By Lieut.-Col. R. Row, M.D. (Lond.), D.Sc. (Lond.), O.B.E.	317
Some Points in the Treatment of Typhus Fever. By Capt. G. R. McRobert, M.D. (Aberd.), M.R.C.P. (Lond.), D.T.M. & H. (Eng.), I.M.S.	318
Cellular Elements in Cholera Stools and their Relative Importance in Diagnosis of the Disease. By Capt. G. C. Maitra, I.M.S., Rai Lal Behari Ganguli, Bahadur, M.B., and J. B. Basu, M.B.	321
A Note on the Cultivation of an <i>Entamoeba</i> from a Monkey (<i>Macacus Rhesus</i>). By Assistant Surgeon B. M. Das Gupta	323
The Treatment of Fractures of the Elbow Joint. By Lieut.-Col. H. Hallilay, I.M.S.	351
A Preliminary Note on the Pharmacology and Therapeutics of <i>Adhatoda Vasica</i> (Baeak). By Major R. N. Chopra, M.A., M.D. (Cantab.), I.M.S., and Sudhamoy Ghosh, D.Sc., F.R.S. (Edin.)	354
Mercurochrome 220 in the Treatment of Malaria. By A. Neave Kingsbury, M.B., B.S., D.P.H., D.T.M. & H., and K. Kanagarayer, I.M.S. (S'pore)	355
Cataract Extraction. By James M. Macphail, M.D. (Glas.)	357
Excision of the Pineal Body of a Monkey under Intra-Arterial Anaesthesia. By Lieut. J. P. Arland, I.M.S. (T.C.)	361
Treatment of Haemorrhoids by Strangulation and Snipping Method. By Capt. D. R. Kehar, I.M.S. (T.C.)	362
The Midwife in India. By Lieut.-Col. C. C. Murison, F.R.C.S.E., D.P.H., D.T.M., I.M.S.	362
A Public Health Policy. By Lieut.-Col. W. C. Ross, I.M.S.	366
Notes on Some Methods for Diagnosis of Hookworm Infection and for Estimating the Egg Output. By Asa C. Chandler, M.S., Ph.D.	403
The Toxicity of Carbon Tetrachloride to Cats. A Warning. By Asa C. Chandler, M.S., Ph.D., and Major R. N. Chopra, M.A., M.D. (Cantab.), I.M.S.	406
"Diagnosis" in Hospitals. By Lieut.-Col. C. C. Murison, F.R.C.S.E., D.P.H., D.T.M., I.M.S.	407
Observations on Cases of Dementia Præcox. By Frank Noronha, M.B., C.M., D.P.M. (Eng.)	415
Experiments on Air Embolism. By A. R. D'Abreu, F.Z.S., I.M.D.	417
Treatment of some Abdominal Conditions with Inflation of Oxygen Gas. By Rajinder S. Grewal, I.M.S. (S'pore)	421
Action of Disinfectants on Microbes: An Interesting Phenomenon. By H. Ghosh, M.B.	423
"Stibosan" (Von Heyden "471") in Private Practice. By Sudhir Kumar Das, M.B., D.T.M. (Cal.)	425

ORIGINAL ARTICLES—(Concluded)

	Page
Acute Inflammation of the Prostate. By Lieut.-Col. Henry Smith, C.I.E., I.M.S. (Retd.)	455
Asepsis. By Lieut.-Col. H. Hallilay, I.M.S.	455
The Staphylococcal Kidney in Childhood. By Major E. H. Vere Hodge, M.B., I.M.S.	459
The Transmission and Etiology of Dengue: A Critical Review. By Asa C. Chandler, M.S., Ph.D.	460
Soil Acidity and Survival of Hookworm Larvæ. By Asa C. Chandler, M.S., Ph.D.	462
A Note on the Toxic Symptoms of Organic Arsenic. By Lieut.-Col. A. Denham White, M.B., B.S., F.R.C.S. (Edin.), I.M.S., and Rai Sahib Sital Chandra Dutt	464
Stibosan (Von Heyden "471"). By L. E. Napier, M.R.C.S., L.R.C.P.	466
Izal in Cholera. By Lal Behary Ganguly	467
Lichen Spinulosus. By Ganapati Panja, M.B.	467
Fungo-Spirochætal affections of Respiratory Passages. By Sarup Narayan Mathur, L.M. & S., and K. N. Zutshi, M.B., B.S.	468
A Summary of the Results of Autopsies held at the Calcutta Police Morgue during 1923-1924 on Cases of Sudden Death. By Major C. A. Godson, M.C., M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S.	469
Chronic Osteomyelitis in Long Bones. By Lieut.-Col. H. Hallilay, I.M.S.	507
Some Points in the Artificial Feeding of Infants. By Major E. H. Vere Hodge, M.B., I.M.S.	509
Extra-Uterine Gestation going to Term with a Living Mother and Child. By Lieut.-Col. P. S. Mills, M.B., I.M.S.	510
Salient Points on Suprapubic Prostatectomy at One Sitting. By M.D. David, M.B., C.M., F.R.C.S.E.	511
A Note on the Value of Iodine Intravenously in the Treatment of Influenza. By Assistant Surgeon C. P. V. Shunker, I.M.D.	513
The Mosquito Factor in the Malaria of Assam Tea Gardens. By C. Strickland, M.A., B.Ch.	514
The Treatment of Malaria with Peracrina 303. By William Fletcher, M.D.	524
A Plea for Research in the Treatment of Squint. By Lieut.-Col. Henry Smith, C.I.E., I.M.S. (Retd.)	559
The Treatment of Incisional Sinuses. By Lieut.-Col. H. Hallilay, I.M.S.	559
Pelvic Measurements in Indian Women. By G. Stapleton, M.D., B.S. (Lond.)	560
Familial Treatment of the Insane. By Major Owen Berkeley-Hill, I.M.S.	562
The Abuse of Emetine. By Capt. G. R. McRobert, M.D. (Aberd.), M.R.C.P. (Lond.), D.T.M. & H. (Eng.), I.M.S.	563
A Lecture on Blood Sugar and Sugar Tolerance. By Capt. S. L. Bhatia, M.C., M.A., M.D. (Cantab.), I.M.S.	565
Bacteriological Study of Stools of 746 Clinical Cholera Cases in Calcutta. By Capt. G. C. Maitra, I.M.S., and J. B. Basu, M.B.	570
A New Organic Antimony Compound for the Treatment of Kala-Azar. By L. E. Napier, M.R.C.S., L.R.C.P.	571
Some Notes on Latrines and Hookworm Incidence on an Estate, as Diagnosed by the Clayton-Lane Centrifuge. By Ronald Senior-White, F.E.S.	572

MIRROR OF HOSPITAL PRACTICE:—

A Case of Frambœsia in the Nicobar Islands. By Major F. A. Barker, M.B., B.Ch. (Cantab.), I.M.S.	29
--	----

MIRROR OF HOSPITAL PRACTICE—(Continued)

A Case of Typhoid Septicæmia without Typhoid Ulcers. By William Fletcher, M.D., and J. E. Lesslar	29
A Case of Muscular Dystrophy, Scapulo-Humoral Type. By Dr. J. P. Cullen, M.D. (Lond.), D.P.H.	31
A Useful Hypodermic Outfit. By Dr. J. W. Tomb, O.B.E., M.D., D.P.H.	32
A Case of Contracture of the Mouth. By N. S. Narasimhan, L.M.P. (Madras), L.C.P.S. (Bombay)	72
A Useful Method of Adapting an Artificial Eye to a Normal or Reconstructed Socket. By R. E. Wright, Major, I.M.S.	120
Two Interesting Cases of Post-Typhoid Sequelæ. By Dr. A. Bayley De Castro	122
An Unusual Case of Malaria. By V. N. Deuskar, L.C.P. & S., I.M.D.	122
Stricture of the Ileo-Cæcal Valve, and Hyperplasia of the Cæcum from Tuberculosis. By Ernest F. Neve, M.D., F.R.C.S.E.	123
Two Cases of Tumour of the Ovary. By S. C. Das Gupta, L.M.S. (Cal.)	124
A Case of Strangulated Hernia. By Sambhu Nath Misra, Rai Bahadur	125
A Case of Pulmonary Embolism. By S. Serhachar	126
A Case of Traumatic Ptosis. By P. B. Karkarey, M.B.	126
Calcium Lactate, a Preventative of Still-Births. By David Perera	126
The Treatment of Malaria in Pregnant Women. By J. Dhairyam, L.M.S.	165
An Interesting Case of Oriental Sore. By D. N. Basu, M.B. (Cal.), D.P.H. (Camb.), D.T.M. (Liverpool)	166
A Case of Acute Gastro-Duodenal Ileus. By Capt. R. V. Rajam, M.B., B.S., Tanjore	167
A Case of Intestinal Obstruction into the Fossa Duodeno-jejunalis. By Capt J. B. Vaidya, I.M.S.	168
A Case of Recurring and Encysted Vesical Calculus. By S. Kanthimathy Nathan, L.M.P.	169
Hæmoplastin in Hæmorrhage. By Kamakhya Prasad Lahiri, L.M.S.	169
Two Cases of Tetanus Treated by Injections of Magnesium Sulphate and Carbolic Acid. By P. D. Samuel, L.C.P.S.	170
An Obscure Case of Pneumococcal Infection. By A. K. Nandi, Captain, I.M.S.	217
An Unusual Complication of Typhoid Fever. By A. T. Roy, L.M.S.	218
An Unusual Effect of Malaria upon the Heart. By Krishan Lal Khera, M.B., B.S.	219
A Case of Triplets. By Binode Krishna Banerjee, M.B.	219
The Dosage of Anti-Tetanic Serum. By M. A. Krishna Iyer, L.M.P.	220
A Tumour of the Abdominal Wall. By K. K. Basu	220
A Note on the Intravenous Use of Urotropine. By Capt. N. N. Ghose, M.B.	221
A Case of Tetanus. By Binode Krishna Banerjee, M.B.	221
A Case of Tick Typhus. By Dr. C. E. S. Norman, F.R.F.P. & S., D.P.H., L.A.H., and C. S. Ramachandran, M.B., B.S.	222
A Case of Abdominal Injury. By Y. S. Row, L.M.P.	269
Two Cases Treated with Intravenous Iodine. By Ram. Pershad, L.M.P.	269
A Case of Muscular Dystrophy Pseudo-Hypertrophic Type. By Major J. B. Hance, O.B.E., M.B., B.Ch. (Cantab.), F.R.C.S.E., I.M.S.	270
A Case of Vesical Calculus formed around an inserted Foreign Body. By Dr. J. W. McK. Nicholl, M.D. (Cantab.)	271
Notes on a large Scrotal Hernia Operated upon under apothesine. By Capt. S. G. Chavan, I.M.S. (T.C.), and Lieut. J. P. Arland, I.M.S. (T.C.)	272

MIRROR OF HOSPITAL PRACTICE—(Continued)

A Case of Ankylosis of Knee-joint cured by Excision. By U. N. Ray Chaudhuri, L.M.S. (Cal.)	273
A Note on the Treatment of Tropical Ulcer. By Major J. P. James, I.M.S.	274
Notes on Two Cases of Encephalitis Hæmorrhagica after Novarsenobillon Administration. By Capt. K. Sen, M.B.	323
A Case of Right-Sided Pleural Effusion Extending into the Epigastrium. By J. N. Sen, M.B. (Cal.), M.R.C.S. (Eng.), L.R.C.P. (Lond.)	324
A Case of Choleraic Dysentery. By P. K. Kurup, L.M.P.	325
A Case for Diagnosis. By N. Chatterjee, M.B.	325
An Interesting Case of Diabetes in Combination with a Condition of Low Kidney-Threshold. By Dr. P. V. Gharpure, M.D. (Bom.)	326
A Case of Kala-azar with Transposition of the Viscera. By K. N. Chatterjee, M.B.	326
Four Unusual Surgical Cases. By Major J. B. Hance, O.B.E., M.B., B.Ch. (Cantab.), F.R.C.S.E., I.M.S.	368
Application of Extension in Cases of Simple Fracture. By P. C. Dutta, M.P.	373
Acriflavine in Otorrhœa. By Shiam Nath Consul, B.Sc., M.B., B.S.	374
Retention of Urine due to Hematocolpos. By Maqbul Alam	374
An Unusual Form of Pseudo-Hernia. By A. Bayley de Castro	375
An Interesting Sign in Retro-Cæcal Appendicitis. By Major A. G. Tresidder, M.D., B.S. (London), I.M.S.	376
A Case of Obstructed Labour by an Intra-Uterine Tumour. By M. N. S. Chetti, L.M. & S.	376
A Case of Internal Strangulation by the Spermatic Cord. By M. N. S. Chetti, L.M. & S.	426
Gangrene of the Testes after Torsion of the Spermatic Cord. By M. N. S. Chetti, L.M. & S.	426
A Case of Pedunculated Papilloma of the Tongue. By H. J. H. Spreadbury, M.B., M.R.C.S.	427
A Swallowed Cork-Screw. By H. M. Hande, L.M.P.	427
A Case of Undetected Gunshot Wound. By Dr. Pitamber Pant	427
A Case of Malignant Pustule. By Ganapati Panja, M.B.	428
A Case of Echis Carinatus (?) Poisoning Failure of Calcium as a Therapeutic Agent. Death in 86½ Hours. By Col. F. Wall, C.M.G., K.H.S., I.M.S. (Retd.)	470
A Fatal Case of Snake-bite (? Echis Carinatus) during Pregnancy. By S. A. S. Chuhan Singh, I.M.D.	471
A Case of Cobra Bite Successfully Treated with Fitz-Simson's Polyvalent Anti-Venomous Serum. By A. C. Bharadwaja, L.M.P., P.S.M.S.	472
A Case of Large Ovarian Cyst not Obstructing Delivery of a Child. By B. Sanjiva Rao, L.M. & S.	473
Interesting Effect of an Insect Bite. By Major P. S. Mills, M.B., I.M.S.	473
A Case of Arsenical Intolerance? By Y. S. Row, L.M.P.	473
A Case of Arsenical Intolerance. By V. N. Deuskar, L.C.P. & S., I.M.D.	473
A Case of Ovariectomy. By Rai Sahib Chhagan Nath	474
A Case of Generalised Blastomycosis. By Ganapati Panja, M.B.	475
A Case of Melanoderma. By Ganapati Panja, M.B.	476
A Fatal Case of Snake-Bite (? Echis Carinatus). Reported by Jemadar Chuhan Singh, I.D.S.M., I.M.D.	477

MIRROR OF HOSPITAL PRACTICE—(Concluded)

A Case of Volvulus of the Ileum. By M. E. Tiru Chelvam, L.M.S.	478
An Interesting Case of Nævus. By Capt. D. M. Bhatavadekar, M.B., B.S., B.M.S., L.M.S. (Hon.)	479
Accidental "Marking-Nut" Dermatitis. By R. W. Scanlon	480
Stone in the Bladder Formed Around a Foreign Body. By Lieut.-Col. J. L. Lunham, M.B., F.R.C.S.I., L.M.S.	527
Amputation of the Penis. By S. C. Das Gupta, L.M.S. (Cal.)	528
Some Surgical Cases. By Rai Sahib Mukand Lal, L.M.S.	529
Observations on a Fatal Case of Liver Abscess. By Lieut. J. P. Arland, L.M.S. (T.C.)	531
A Case of Accidental Abdominal Injury. By K. V. Joglekar, M.B., B.S.	532
A Case of Hydatid Cyst of the Right Parotid and Submaxillary Glands. By N. P. Shrivastava, L.M. & S. M.B., B.S.	532
An Interesting Case of Perineal Fistula. By B. R. Garg, L.M.P.	575
An Enlarged Wandering Spleen Mistaken for an Ovarian Tumour. Sple- nectomy and Recovery. By J. N. Sen, M.B., (Cal.), M.R.C.S., (Eng.), L.R.C.P. (Lond.)	576
A Unique Case of Multiple Neuro-Fibromata. By Mrs. E. Bernard Carr.	577
Multiple Soft Fibromata of the Face. By Ganapati Panja, M.B.	578
A Simple Cure for Leucoderma. By P. Bhaskara Rau, L.M.P.	578
An Unusual Case of Malaria. By Nisanath Ghosh, M.B. (Cal.)	579
Pneumonia and Cellulitis Treated with Intravenous Iodine. By S. N. Datta, L.M.P.	579
Notes on Cases of Acute Yellow Atrophy of the Liver. By Y. S. Row, L.M.P.	580
The Up-Going Toe. By Capt. M. S. H. Mody, M.B., B.S. (Bom.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), D.T.M. & H. (Lond.)	581
Syphilitic Dyspnoea Simulating Asthmatic Fit. By M. G. Ramachandra Row, M.B., C.M.	581
A Case of Malarial Prostatitis with Reflex Retention of Urine. By Capt. S. L. Chopra, M.B., B.S.	582
A Case of Resuscitation after Cessation of the Vital Functions for over 15 Minutes. By Major N. C. Kapur, B.A., L.R.C.P. (Lond.), M.R.C.S. (Eng.), L.M.S.	582
A Case of Bullet Wound of the Chest Followed by Pleurisy with Effusion. By Ram Labhaya, L.M.S.	583
An Interesting Case of Transverse Presentation. By Madan H. Jhaveri, M.B., B.S. (Bom.)	583
Intra-Muscular Injection of Urea Stibamine. By S. Kundu	583
A Case of Pernicious Malaria Treated with Quinine Intravenously. By Khagendra Nath Chatterji, M.B.	584

SUPPLEMENT.

THE INDIAN MEDICAL YEAR, 1924.*

THANKS to the kindness of a considerable number of contributors, it is possible to present a review of the Indian medical year, 1924, rather in the form of a symposium by several authorities than as a résumé by a single writer.

DISEASES OF THE TROPICS, EPIDEMIOLOGY, SYMPTOMATOLOGY AND TREATMENT.

Malaria.

One of the greatest advances made in recent years in connection with malaria is the introduction in the Punjab of malarial forecasts, year by year, by Lieutenant-Colonel C. A. Gill, based on his study of the meteorological conditions under which malaria spreads. For four years in succession malarial forecasts have been made for the Punjab, and have turned out to be remarkably accurate. Given such an accurate forecast, it is possible to mobilise personnel at the danger areas in advance and to take measures beforehand, and these forecasts are now acted upon by the public health organisation of the province, and by the Director of Medical Services, India. The publication of Colonel Gill's forthcoming book on the rôle of meteorology in epidemic malaria will be awaited with much interest.

Lieutenant-Colonel S. R. Christophers, in a paper which deserves to become a classic, gives a vivid description of the conditions present in a hyper-endemic area (Singhbhum). There is a regular co-ordinated sequence of events, a precise study of which constitutes what is almost a new science. During the first two years of life every child in the community suffers almost continuously from acute febrile infestation; parasites to the number of some 10,000 per c.mm. being continuously present in the blood, and the spleen enlarged some 5 cms. below the costal margin. Next comes a stage of immune infestation, which lasts throughout childhood into adult life; by about the third year of life—or of age—residence in the case of children who have come to live in the area—the number of parasites has dropped to about 1,300 per c.mm., and fever occurs only about once a fortnight, the spleen, however, being even larger than before. Among the adults the spleen rate was 50 per cent., the number of parasites only about 100 per c.mm. of blood, and the adult has become immune and is afebrile; the condition indeed resembling the "salting" of animals which occurs in trypanosomiasis and piroplasmiasis.

The same author, with Rai Sahib Kazan Chand, sets up a standard method of measuring enlarged spleens in doing survey work, the measurement being expressed in cms., and a table given for correction in accordance with the sitting height, age or nipple-umbilicus line. Measurements are recommended from the lower pole of the spleen to the umbilicus and to the mid-line of the body, and a standard chart given together with a notation which gives standard results of effectiveness and precision. In a further paper, Colonel Christophers also gives the frequency distribution of measurements of enlarged spleens in a malarious child community, and raises the question of the relationship of the size of the spleen to the number of attacks and relapses suffered.

Hill-station malaria has attracted a good deal of attention during the year. In a study of malaria in Shillong, Lieutenant-Colonel T. C. McCombie Young shows *A. maculatus* to be the important local carrier, and that it breeds in the river pools in the Um Kra stream, the rice fields being less important. Should the rainfall in the early phase of the monsoon be heavy,

these pools are scoured out and the year is relatively non-malarious. A system of contour drainage is recommended. The same subject is also dealt with by Major H. E. Shortt. The malarial season in Shillong is from June to October; and of late years the disease has become increasingly prevalent. The spleen rate among the indigenous Khasis is very low, but the Pasteur Institute patients constitute a continuous reservoir of the infection in the neighbourhood of the Um Kra and Um Shirpi streams where *A. maculatus* breeds. These streams should be canalised.

On Ambootia Tea Estate, Kurseong, Dr. C. Strickland shows that *A. maculatus* and *A. willmori* are the carriers, and there is a close relationship between rainfall and malaria. Should the early rains be heavy, the breeding places are scoured out and a year of low malarial incidence follows; in fact the curve of severity of the monsoon and of malarial incidence in the next year are in an inverse relationship. In a second paper he contrasts the conditions present in Kurseong and Shillong respectively.

An interesting account of the anti-malarial measures in connection with the Back Bay reclamation scheme, Bombay, is given by Captain B. S. Chalam. In view of the great prevalence of malaria in connection with previous reclamation schemes, Colonel Christophers was invited to visit Bombay in 1923 in connection with the Back Bay scheme, and advised the services of a whole-time officer. The organisation instituted has grappled very successfully with the problem, the whole area being divided into sectors, each of which is covered twice a week by the search and larvicide parties respectively. The chief carriers are *A. stephensi*, *A. culicifacies* and *A. vagus*, with *A. rossii* also prevalent; and the chief breeding places which have required attention are the mouths of the sludge pipes, joints of pipes where leakage occurs, fissures in the drying sludge, and depressions in the new land surface. Work has also been necessary in the adjacent areas in Colaba, and much public health propaganda work is being carried out. Admissions to Colaba hospital for malaria among British troops have fallen from 973 in 1921, to 418 in 1923, and to 169 in 1924.

In Assam, Dr. Strickland incriminates *A. umbrosus*, which breeds in cut bamboo stumps, as an important vector, whilst in Madras, Dr. D. A. Turkhud reports, that special measures had to be taken to deal with epidemic malaria in the work of the Forest Department at Sappal Hill and Top Slip. Drs. Ramaswami Iyer and K. P. Menon were specially trained and sent to the two areas respectively, and have submitted detailed reports and recommendations for the consideration of government. What can be accomplished, even by partial measures alone, is described by Major J. A. S. Phillips in connection with five towns in the U. P. Here, although all that was desirable could not be carried out, yet the results of partial measures during the last 14 years or so have been as follows:—in Saharanpur a reduction of the spleen rate from 79 to 7 per cent., in Nagina from 79 to 13 per cent., in Kosi from 81 to 42 per cent., in Meerut from 6 to 1.3 per cent., and in Lucknow from 2.2 to 1.6 per cent., together with greatly reduced fever rates.

Turning to symptomatology, R. K. Handa describes a case of malaria associated with Raynaud's disease and fatal gangrene of the legs; whilst Major J. A. Sinton and R. B. Lal deal with albuminuria in malaria. Its incidence in 64 malignant tertian cases treated between August and mid-September was 18.7 per cent., and in 110 cases treated between mid-September and mid-October was 12.4 per cent. The combination of quinine with alkalies in the doses given had no deleterious effect on the kidneys, and the results show a slight diminution in the incidence of albuminuria in the cases treated with alkalies. Major Sinton has introduced a most ingenious method for enumerating the parasites and leucocytes in malarial blood. A standard suspension of the nucleated red

* Unless otherwise stated, the commissioned officers referred to are all officers of the Indian Medical Service.

corpuscles of fowls is made in 1 in 3,000 perchloride of mercury solution, so that 1 c.mm. = 20,000 cells. The malarial blood is then mixed with an equal volume of this suspension, and the mixed fluid spread in a thick smear, when, as the number of nucleated cells is known, the number of parasites or leucocytes can easily be arrived at. Major T. A. Hughes found a condition of latent hæmolytic jaundice to be present in four cases of hepatic cirrhosis with enlargement of the spleen and ascites by the van den Bergh test, and considers that a similar condition may be present in individuals continually resident in malarial districts, who show no clinical signs of active malaria. Working with Major Sinton, a study of the functional capacity of the liver in malaria was made, as measured by the lævulose tolerance test. There may be some disturbance of the glycogenetic function of the liver in a certain number of ordinary acute cases of malaria, but the degree of inefficiency found was not marked. In cases showing pernicious symptoms the inefficiency would probably be greater. The ingestion of glucose or lævulose is indicated in all cases of malaria, more especially in severe cases, to protect the liver cells and prevent further damage to the other functions of the liver, which are protected by the glycogen reserve of this organ.

In continuation of his former studies, Major Sinton with sub-assistant surgeon J. D. Baily, I.M.N., draws attention to the "acidosis"—or rather lowered alkali reserve—in malaria. The amount of sodium bicarbonate required to render the urine of healthy Indians alkaline to litmus was found to be on an average 6.5 grammes, whereas in a series of ordinary cases of malaria the corresponding amount was found to be 14 grammes.

Turning to treatment, Majors H. W. Acton, and R. Knowles advocate a standard treatment for malaria with Indian cinchona febrifuge. The diagnosis should first be established by finding the parasite in blood films,—(in which connection the thick film method advocated by Knowles and Das Gupta is exceedingly useful), and the patient should then be continuously cinchonised for 31 days, the urine being tested to ensure that he is taking his medicine. The timing of the dose is important; it should be given on an empty stomach 2 to 2½ hours after meals. For algid, comatose and severe cases, 7½ to 10 grains of quinine bihydrobromide, given intravenously in 15 to 20 c.c. of saline, is the best line of treatment, the patient usually being able thereafter to take the cinchona febrifuge prescription orally. Major O. A. R. Berkeley-Hill reports that of 35 cases of benign tertian malaria treated orally with cinchona febrifuge on the above lines, and carefully watched over a successive period of some months, only 4 relapsed—at intervals of from 2 weeks to 2 months after completing treatment. He is collecting observations for publication at the Ranchi Mental Hospital where patients can be kept under observation for considerable periods. Based upon Acton and Knowles' formula, Dr. T. H. Bishop advocates the following prescription, which is now in use all over the E. B. Railway system, and which he states is pleasanter and far more palatable than a quinine mixture:—

Pulv. cinchona febrifuge, 10 grains; acidi citrici 20 grains, magnesii sulphatis 20 grains, spiriti anisi 10 minims, syrapi simplicis to half an ounce.

Dose; half oz. b.d. or t.d.s. two hours after food.

Dr. U. N. Brahmachari deals with the treatment of difficult cases of malaria. Quinine salts being markedly hæmolytic, he uses an anti-hæmolytic solution for intravenous administration, of the following composition:—

Quinine alkaloid 5 grains, alcohol 50 minims, urethane 3 grains, calcii chloridi 7½ grains, glucose 300 grains, and normal saline 300 c.c.

This should be administered slowly at the rate of not more than 10 c.c. per minute and might prove suitable for cases of blackwater fever.

Majors R. N. Chopra and Knowles, with Assistant-Surgeon J. C. Gupta record the absolute failure of *Vitea peduncularis* in the treatment of malaria, whilst

Dr. Bayley-de Castro records the case of a woman six months pregnant, suffering from mixed benign and malignant tertian malaria, together with typhoid fever, who recovered after treatment with intravenous quinine.

Plague.

Most of the work of the year has been on anti-plague vaccines. Major W. D. H. Stevenson and the late Khan Bahadur R. J. Kapadia record the results of inoculating rats with vaccine. Not only does the inoculation protect, but even in such rats as get plague thereafter it delays the fatal issue. The immunity conferred varied with the dose given, and the potency of the vaccine was found to vary with the virulence of the strain used. Long stored vaccines gave but little reaction and are of low toxicity. Vaccines incubated 6 weeks to 2 months are much more potent than vaccines incubated for more than 3 months. Vaccines 1 year and 2 months old were still strongly protective; protective value was even retained in vaccine 2 years old. It is recommended that vaccines should be used incubated from 6 weeks to 2 months, and kept after sterilisation for some months.

From Parel Lieutenant-Colonel F. P. Mackie reports on the work of Major Morrison, Captain B. P. B. Naidu (T. C.), and Dr. C. R. Avari, as follows:—

"From the middle of August 1923, Major Morrison with the assistance of Dr. Naidu (who received a grant from the Indian Research Fund Association for this purpose) and Dr. Avari carried out experiments until the middle of April 1924, when he went on leave.

"These experiments were continued throughout 1924 by Dr. Naidu and Dr. Avari with the assistance of Captain Malone who joined this Laboratory in April 1924.

"The object of these experiments is to discover some means by which Haffkine's plague prophylactic may be improved so that its potency may be increased, while its 'toxicity' (as judged by the local and general reaction which follows its inoculation into man) may be diminished.

"Haffkine's plague prophylactic is a whole vaccine composed of the culture medium (the nutrient broth) with the plague bacilli grown in it for a period of six to eight weeks and the products of their metabolism. This is sterilised by heat and 0.5 per cent. carbolic acid is added to ensure its sterility. Four c.c. of this vaccine are administered subcutaneously for a prophylactic dose. Since its introduction as a prophylactic measure, this vaccine has undergone little or no change in the method of its manufacture.

"(a) The first series of experiments was to determine which of the constituents of Haffkine's prophylactic fluid was responsible for the toxic and immunising properties.

"The prophylactic when centrifuged or allowed to settle separates into a clear supernatant fluid and a compact sediment consisting of bacillary debris.

"The whole prophylactic, the sediment and the supernatant fluid respectively, for each brew concerned, were tested and compared with regard to their toxic and immunising properties.

"The results of these experiments are:—

"1. Rats imported from Madras for these experiments, when infected with 0.003 milligram of spleen of a plague-infected rat, showed a mortality of 95.3 per cent. within ten days of infection.

"2. Nutrient broth from which Haffkine's prophylactic is made is not toxic to rats and it has no immunising value.

"3. The whole prophylactic given in a dose of 0.5 c.c. killed 35 per cent. of the rats from toxæmia and produced an immunity which reduced the mortality from 95.3 per cent. to 55.6 per cent.

"4. The sediment from 0.5 c.c. of Haffkine's prophylactic showed neither toxic nor immunising properties.

"5. The supernatant fluid caused a mortality of 19.8 per cent. from toxæmia and produced an immunity which reduced the mortality to 53.11 per cent.

"(b) Anti-plague vaccines prepared from agar cultures, are manufactured for prophylactic use in Germany, France and England.

"Therefore, a series of experiments was next carried out to compare the toxicity and protective value of vaccines prepared from agar cultures with Haffkine's prophylactic. The results of these experiments are:—

"1. When compared with 0.5 c.c. of Haffkine's prophylactic, agar cultures treated with formalin and acetone are not toxic and show no evidence of immunising power, even in doses of 12.5 milligrams.

"2. Agar cultures treated with chloroform vapour and 1 per cent. carbolic acid show no immunising power until the weight of the dried vaccine exceeds 13.6 milligrams.

"3. Agar cultures treated with 1 per cent. carbolic acid possess immunising properties when used in a dose of 8 milligrams.

"4. Agar cultures sterilised and carbolised in the same way as Haffkine's prophylactic, when used in doses of 4 milligrams, possess toxic and immunising values equivalent to 0.5 c.c. of Haffkine's prophylactic.

"5. Only with heated vaccine does the toxicity regularly increase with the dose.

"(c) Besredka's method of immunisation by oral administration of vaccines against typhoid, dysentery and cholera has been recently tried by M. Legar and A. Baurly in the case of plague, who claim some measure of success in their experiments. It would be a great advance in prophylactic methods if the vaccine could be administered orally, as subcutaneous inoculation excites a good deal of inflammatory reaction.

"A series of experiments were undertaken on the lines suggested by M. Legar and A. Baurly.

"Results of these experiments are:—

"1. Rats which are very satisfactory for estimating the prophylactic value of plague vaccines, when administered subcutaneously, are not suitable animals for the oral administration of bile and vaccine. They have not been induced to eat baits prepared with bile, and when bile is administered by a catheter they apparently die readily of œdema of the glottis.

"2. Guinea-pigs can be fed with bile by a catheter. The treated guinea-pigs receiving doses similar to those given by M. Legar and A. Baurly afford no evidence that any immunity is conferred by the oral administration of bile and the plague prophylactic, or by the oral administration of the plague prophylactic alone.

"As these experiments do not demonstrate any superiority of agar-grown vaccines over Haffkine's plague prophylactic, and as the method of preparing vaccines from agar cultures on so large a scale as is done at this Laboratory is not feasible, further enquiries are confined to the prophylactic, as to how the toxicity of the vaccine could be reduced and its immunising power increased.

"The factors which are considered to have most influence on the efficacy of the plague prophylactic are:—

"(1) The medium employed for the growth of plague bacilli;

"(2) the seed virus and its virulence;

"(3) the period of incubation; and

"(4) the period of storage.

"Investigations are now in progress to determine if the prophylactic can be improved by modifying one or more of the above factors."

It will be seen from Colonel Mackie's report that there is every hope of considerable improvement in the vaccine in the near future.

In treatment, Majors C. J. Stocker and G. F. Graham have studied the use of a sensitised vaccine in a local outbreak at Hoti Mardan. The agglutinating powers of the sera used were tested with the washed sediment of Haffkine's vaccine, pigeons being used for serum production. It was found best not to heat the vaccine

after sensitisation. The following are their results:—

17 cases not previously inoculated; treated with the new vaccine; 1 died = 8 per cent.,

18 not previously inoculated; not treated; 11 died = 61 per cent.

12 cases previously inoculated; treated with the new vaccine; 1 died = 8 per cent.

whilst the general mortality in plague in inoculated persons is about 12 per cent. If a sensitised vaccine will reduce the mortality in plague from 61 to 29 per cent., it may prove a very valuable therapeutic agent.

Several workers are treating plague by intravenous injections of iodine, but as far as the writer is aware no large series of results has as yet been published. R. D. Pal reports a case of acute but transient œdema of the glottis following on such an injection.

The Milroy lectures on plague, were delivered by Lieutenant-Colonel W. Glen Liston, and form an admirable account of the historic work of the Plague Commission.

Cholera.

Dr. P. T. Patel gives an account of the 1923 outbreak in Bombay. The infection was imported with Haj pilgrims from Bengal, and 182 cases were admitted with 58 deaths, a mortality of 32 per cent. Treatment was by hypertonic saline, permanganate pills, atropine hypodermically and kaolin emulsion. The cholera vibrio was isolated from 129 of the cases.

Majors Acton and Chopra describe the nature and pharmacological action of the cholera toxin. The vibrio can liquefy gelatine, reduce the amino-acid tryptophane to indol, and decarboxylate amino-acids into poisonous bases. A 10 days old culture in veal broth contains both volatile and non-volatile bases. When separately tested, the volatile bases were found to be almost non-toxic, but caused tonic contraction of the rabbit's intestine. The non-volatile bases, and especially their arginine fraction, are toxic; and cause a fall of blood pressure, an oxytoxic action on the pregnant uterus, thus causing miscarriages, and have a direct action on the secreting tubules of the kidney. The production in experimental animals of every symptom of cholera by these bases, freed from all bacteria, is a striking example of the exactness of modern biochemical methods. The optimum conditions for the production of the poisonous bases were found to be a supply of the necessary amino-acids, a pH on the alkaline side, and a liberal supply of oxygen.

Dr. J. W. Tomb contributes further figures with regard to his essential oils' mixture. In 1923 in the Asansol mining area there were 345 cases of (clinical) cholera, 2,156 contacts of these cases were treated with the mixture, and not a single case of cholera occurred among them; had the experience of previous years been repeated, some 132 cases should have occurred among this number of contacts. Lieutenant-Colonel F. J. Palmer, R.A.M.C. (retd.), is a strong advocate of cresol; 1 to 4 minims according to age, given every quarter of an hour in the same number of ozs. of water for two hours; then at increasing intervals of $\frac{1}{2}$ hour, 1 hour, 2 hours, etc., the amount of cresol being gradually reduced. As the patient convalesces, the greatest care must be taken against too rapid an increase of diet; whilst for uræmic cases nasal tube feeding may have to be resorted to. Care should be taken in selecting the brand of cresol used, sanitol being advocated. He records 61 cases treated with 12 deaths, 19.6 per cent. mortality. Lieutenant-Colonel W. C. Ross gives comparative figures, on only a small scale, however, for different methods of treating cholera. He holds that for general use, and especially in village practice and outlying dispensaries, kaolin is the best line of treatment, supplemented with permanganate drinks; 2 deaths in 13 cases. The same conclusion is come to by S. C. Chatterjee on four small series of cases, treated by different methods and compared as to results.

In Madras a severe outbreak at Vaniyambadi in N. Arcot district was investigated by Assistant Surgeon N.

Seshadrinathan; the water supply was found to be infected, but prompt measures arrested the outbreak.

In connection with his enquiry into cholera in the coal-fields, Captain G. C. Maitra writes:—

"An enquiry into the bacteriology of clinical cholera cases in the Jheria coal-fields showed that while it was relatively easy to recover cholera vibrios from the stools of cases in an epidemic outbreak, vibrios were often found absent in the stools of sporadic cases both microscopically and culturally. This necessitated a study of the bacteriology of suspected cholera cases in one of the Calcutta hospitals under favourable laboratory facilities. A year's experience shows that the vibrios disappear from the stools more rapidly than they are usually thought to do. In a series of 500 cholera cases examined in Calcutta within 48 hours of onset, they were found only in 84 per cent. of the stool films and then only after very careful search. On the other hand 98 per cent. of these stool films showed necrosed epithelial cells from the intestinal mucosa for which the cholera poison has a selective action. These cells persist even after the vibrios have disappeared and constitute an important point in the cyto-diagnosis of the cholera group of diseases.

As regards the cultivation of cholera vibrios from stools, complicated and differential media, such as MacConkey's and Dieudonné's were found of very little use. Ordinary agar, either alone or in combination with 0.5 per cent. bile-salt (sodium taurocholate) was quite enough for the isolation of vibrios from the majority of cases. The chief obstacle to a successful culture was not so much the organisms of the *coli* group as the putrefactive bacteria of the *proteus* group. The activities of the latter could however be checked by adding a small quantity of bile-salt, with very little interference to the growth of the vibronic colonies.

The employment of simpler media greatly helped the bacteriological study of suspected cholera cases in Calcutta. Out of a total of 750 cases examined during the year, positive cultures of vibrios were obtained in 80 per cent. of cases. Of the positive series 85 per cent. were cases of true cholera due to Koch's comma vibrio, and 15 per cent. were cases of para-cholera due to cholera-like vibrios. The majority of these cholera-like infections were found associated with benign cases of clinical cholera and most probably they constituted the bulk of the sporadic cases observed in the coal-fields.

The possibility of inducing immunity against cholera and bacillary dysentery by oral vaccination was tested on rabbits. The protection offered against cholera by this method was found to be more pronounced than that against dysentery. These experiments have been continued with a view to omitting the ox-bile which was originally recommended by Professor Besredka in combination with the cholera vaccine. A combination of Shiga and cholera vaccines gives almost the same result on experimental animals as bile and cholera vaccine. But the number of experiments to date is too small to warrant definite conclusions.

A polyvalent vaccine containing representative strains of dysentery bacilli found locally has been issued lately to 3 selected jails in Bengal for trial. The time is not yet ripe for a consideration of the results."

Dysentery and Amœbiasis.

Two important papers are those by Lieutenant-Colonel J. Cunningham and Assistant Surgeons J. H. Theodore and K. Y. Krishnan on latent dysentery. These workers show that if the stools of a general population be microscopically examined, it is found that a certain percentage are passing mucus in the stools without accompanying symptoms, a condition of latent dysentery. Twelve consecutive examinations are sufficient to identify all the latent dysentery carriers in the population of a given institution, and to establish the "dysentery index." Such indices were 19.8 per cent. in jails in Eastern Bengal, 27.6 per cent. at Cannanore and 30.9 per cent. at Bellary among Moplah prisoners. The detection and

isolation and treatment of such cases is of the greatest importance as a practical measure of dysentery control, and the method is well worth adopting by any jail superintendent who is troubled with dysentery in his jail. No less than 63 out of 234 prisoners working in cook-houses were found to be latent dysentery cases. A further practical application of Colonel Cunningham's method is that by Assistant Surgeons N. Seshadrinathan and J. H. Theodore in connection with an outbreak of gastro-enteritis among the Moplah prisoners at Alipuram jail. A thorough examination of cases, contacts, convalescents and carriers showed that the epidemic was only an acute exacerbation of latent dysentery due to Flexner's bacillus. The epidemic was rapidly brought under control by the use of polyvalent anti-dysentery serum, inspection of stools for the identification and segregation of latent cases, protection of water supplies, and the strict isolation of the kitchen gang, with elimination of latent dysenteries from them.

With regard to "heathy" *E. histolytica* carriers, Majors Acton and Knowles claim that the condition is not always as free from symptoms as is usually supposed. There is always present some degree of ulceration of the colon mucosa, and such ulceration may lead to hæmolytic streptococci from the gut invading the blood stream. The results of such "streptococcal showers" in the blood stream may be unexpected symptoms, such as asthma, leucoderma, urticaria, sciatica, giant urticaria, etc. In these conditions the stools should always be examined for *E. histolytica* cysts, because if such are found and the condition treated, the primary disease may also be benefited.

A study of the bacillary carrier question by Assistant Surgeon H. Rai in the villages around Kasauli gave positive findings of dysentery bacilli in 5.4 per cent. of 201 stools examined, and showed that some 4 per cent. of the village population were bacillary dysentery carriers, chiefly of organisms of the Flexner group. Much of what is loosely written down as hill-diarrhoea is almost certainly Flexner bacillus infection.

The publication of Fletcher and Jepps' "Dysentery in the Federated Malay States," reviewed in our issue for last September, is an incident of the year. The book is one of great value and should be in the hands of every medical practitioner in the tropics.

Majors Acton and Knowles, in an article on the dysenteries of India illustrated with a colour plate, attempt to put together in a nutshell the lessons of the war and of the huge volume of work of recent years on dysentery. There have been considerable changes at the Calcutta School of Tropical Medicine in the treatment of amœbic dysentery, however, since that paper was published. At the present time comparative studies are in progress as to the relative value of (a) emetine; (b) kurchi; (c) stovarsol; and (d) yatren in cases of *E. histolytica* infection, with a view to collecting observations on a large scale for comparison. It is as yet perhaps too early to make any definite statement, but the results to date with stovarsol, (May and Baker) seem very promising. Up to date 8 cases of amœbic dysentery and two of lambliaosis have apparently cleared up completely on stovarsol treatment. The treatment is simplicity itself, the administration twice a day of one 4 grain tablet of stovarsol orally with food. The drug is at least worth an extended trial.

(In connection with the above two papers by Majors Acton and Knowles, Messrs. Thacker, Spink have recently published a small handbook on the dysenteries of India by these authors, illustrated with colour plates of intestinal protozoa in both the vegetative and encysted phases, and dealing with the whole subject for the general practitioner and laboratory worker in this country at Rs. 1-8; a first essay in the production, it is hoped, of a series of such small text books on tropical diseases, published at a price to be within the reach of the Indian medical student and general practitioner.)

In the treatment of amœbiasis with emetine there are certain dangers which must be guarded against. Thus, as Major R. N. Chopra, Drs. B. N. Ghosh and P. De show, the drug is a general protoplasmic poison, with special toxicity for the cardiac muscle, and with a selective destructive action on the endothelium of the capillaries throughout the body. Prolonged administration also causes congestion and fatty infiltration of the liver and kidneys. The administration must be controlled and watched. In the paper by Acton and Knowles a course of six days of administration of large doses of bismuth carbonate together with emetine subcutaneously was advocated; but both workers now prefer a continuous nine days' course of the bismuth treatment, together with one grain of emetine a day, given intravenously. Major F. J. W. Porter, R.A.M.C. (ret.), also advocates the intravenous use of emetine, giving it in half-grain doses twice daily in acute amœbic dysentery, with or without 1/12th of a grain of morphia; and in liver abscess in doses of 1 grain twice a day intravenously. S. Mulherji draws attention to the advisability of simultaneous or preliminary anti-helminthic treatment in cases of dysentery in India, since such infections are frequently present as complications.

Captain A. Sargood Fry records the cure of two remarkable cases of large amœbic abscess of the liver by emetine therapy alone, unaccompanied by any aspiration. There seems to be no necessity to aspirate in all cases. Once the entamœbæ in the liver tissue are killed, inasmuch as the pus is sterile, it will behave like a healing tubercular abscess and undergo spontaneous absorption and resolution. In both patients co-existing helminthic infections required treatment.

Lieutenant-Colonel J. W. D. Megaw and Captain G. C. Maïtra draw attention to chronic dysenteric peritonitis as a possible cause of ascites in Indians and the condition of "morbus bengalensis" described so many years ago by Norman Cheevers. The chief causes of ascites in India differ markedly from those in England; and many patients are encountered who show no hepatic cirrhosis, but give a history of dysentery. Of 50 such cases investigated 31 gave positive agglutinations to Flexner's bacillus at titres of from 1 in 16 to 1 in 80, whereas controls showed agglutinins in a much smaller proportion of cases.

Spurue.

The problem of the real causation and ætiology of spurue still remains unsolved, but a serious attempt is being made to solve it at the Bombay Bacteriological Laboratory. Lieutenant-Colonel F. P. Mackie writes as follows:—

"Some preliminary investigations into the causation of spurue have been in progress for more than a year and a considerable body of evidence has been collected, particularly as regards the vexed question of *Monilia* infection of the intestinal tract. Numbers of type cultures have been obtained from Europe and have been compared with strains isolated locally. This aspect of the work has been in the hands of Colonel Mackie and Dr. Chitré and the classification of yeasts is being continued.

"The question is a very complex one and the whole question to taxonomy is in a chaotic state.

"An attempt is being made to simplify the classification of intestinal yeasts, which has become needlessly complicated by the acceptance of minute variations in sugar reactions being accepted as indicating special or generic difference. The observers have not satisfied themselves that there are yeasts which are in any way specific to spurue and on this point are at variance with the findings of Ashford and others.

"They also consider that *Monilia* infestations are in all probability incidental to the development of spurue, and are not causative, though their presence may explain certain of the intestinal symptoms and signs.

"The serological side of the yeast problem is being

taken up by Dr. N. H. Fairley, whilst the intestinal flora is being studied by Dr. Goré.

"The biochemical aspect of spurue is receiving attention at the hands of Dr. Fairley and Colonel Mackie, assisted by Mr. Malandkar who is temporarily in charge of the recently established biochemical unit.

"Some work has already been done on the fat content of the faeces which points to non-absorption or excessive secretion of intestinal fat and a probable deficiency of lipase. Other biochemical problems which await investigation are the fat and calcium content of the blood, the functional efficiency of the stomach, intestine, liver and pancreas.

"The clinical aspect of the disease, together with its hæmatology and morbid anatomy, are also being investigated, but it is probable that it will need at least two more years of work before any publication dealing with this highly complex disease will be justified."

Enteric Fevers.

A valuable paper is that by Lieutenant-Colonel J. W. Cornwall and Assistant Surgeon H. M. Lafrenais, I.M.D., on the mechanism of infection by *B. typhosus*. These workers find that the stomach of the rabbit presents an absolute barrier to experimental infection, but that if the bacilli are introduced directly into the jejunum infection takes place and typhoid bacilli can be found in the circulating blood within an hour. Given certain conditions, the *B. typhosus* will pass the stomach barrier of man; if these do not prevail, however, the stomach presents an absolute barrier. The bacillus can pass through the skin, also probably through the conjunctiva and nasal and pharyngeal mucosa, but these are unlikely channels of infection in man. If any local immunity of the intestinal epithelium can be produced, it can be tested for by the intra-jejunal injection of living typhoid bacilli. The immunity in man depends on (a) the ability of the ectoderm to prevent passage of bacilli through it; (b) the ability of the cells of the mesoderm to withstand toxins. *B. typhosus* may occasionally lie latent for many months in the tissues (of a rabbit), and then suddenly break its bounds and cause a fatal issue.

In diagnosis A. Bayley-de Castro emphasises the great value of Marris's atropine test. Four cases were tested between the 9th and 14th day of disease, and all gave markedly positive results.

Major J. A. Cruickshank draws attention to the possible value of prophylactic inoculation of convalescent enteric cases in order to reduce the percentage of carriers in any given military or other population, basing his observations on 1886 convalescent cases studied at Parel during the war. Those not inoculated prior to the onset of enteric fever gave a carrier incidence of 3.2 per cent.; those previously inoculated of only 0.5 per cent.

With regard to the causative bacilli, Lieutenant-Colonel J. W. Cornwall has studied the changes in media produced by the *B. typhosus*. Milk media, however prepared, as long as the pH is not below 7.2, show acid production within the first 24 hours. Milk clarified by sodium citrate becomes milky during the growth of certain species of bacteria in it. If the pH is lower than 7.2, however, acid production is not observed within the first 24 hours. After sterilisation of peptone water, glucose-peptone water and rabbit serum at 37°C., spontaneous changes may occur in the reaction of the media. Dr. S. N. Goré at Parel has been studying the colityphoid group of bacteria, and proposes a new method of classification. Colonel Mackie reports as follows:—

"Dr. S. N. Goré is studying the aerobic bacilli isolated from faeces obtained from healthy persons and from cases of diarrhoea, dysentery and spurue, according to the method of procedure he has outlined for the classification of such bacilli (vide *Indian J. Med. Res.*, July, 1924).

"He has classified these bacilli into three principal groups according as to whether they ferment glucose

and lactose or not. Group I comprises bacilli which completely ferment glucose and lactose, like those belonging to the colon-aerogenes group; Group II, bacilli which completely ferment glucose only, like those of the paratyphoid-Gaertner-Morgan group; and Group III, bacilli which only partially ferment glucose, like those of the typhoid-dysentery group. These three groups he has designated by the formulæ GL, G, and g, respectively.

"The results of the study of 120 samples of fæces are summarised in the following table:—

No. of samples of fæces.	Samples of fæces obtained from:—	Number of samples of fæces containing bacilli belonging to groups:—			
		GL.	GL and G.	GL and g.	GL, G and g.
17	Healthy persons ..	17	Nil.	Nil.	Nil.
17	Healthy inmates during a small epidemic of typhoid fever in a reformatory.	10	6	1	Nil.
17	Cases of diarrhœa ..	11	6	1	Nil.
18	Amœbic dysentery ..	4	8	4	2
27	Non-amœbic dysentery.	2	6	10	9.
23	Sprue ..	12	6	3	2

"He found that only a very small proportion of the bacilli falling in the groups to which the well-established pathogenic intestinal organisms belong, agglutinated with the antisera of the latter bacilli. Further study on this subject is in progress."

Kala-azar.

Dr. L. E. Napier kindly contributes the following review:—

"**Epidemiology.**—Geographical distribution:—At the beginning of the year Captain J. B. Hance reported three cases of kala-azar from Dera Ismail Khan, one case being confirmed by spleen puncture findings, in men who had never been away from the North-West Frontier Province. The observation is so far an isolated one.

"From Assam the Director of Public Health reports that a number of foci of the disease have been found in Lakimpur District, a district which was previously supposed to be free from the disease. A survey in Cachar has shown that 117 out of 737 villages surveyed are infected and the survey in Sylhet indicates that the disease is much more common there than was previously supposed.

"Age incidence:—Dr. S. C. Basu, analysing 1,600 cases in villages near Calcutta diagnosed clinically, showed that the frequency distribution curve has its peak at the second quinquennial period, falling almost to the base line by the eighth quinquennial period.

"Dr. Basu also described an outbreak of fever with a typhoid-like onset, occurring spontaneously in the month of May in a village in Bengal, which he concludes on clinical grounds, supported by a spleen puncture finding in one case, to be an outbreak of kala-azar.

"During the year Lieutenant-Colonel T. C. McCombie Young published a book on 'Kala-azar in Assam.' In this most important publication he gives the history of kala-azar in Assam since its introduction and the means by which the Public Health organisation of the province has dealt with it; he describes the partial success of the isolation methods and the fuller success of treatment on a large scale. Many epidemiological facts have been collected which are interesting to the general

reader and which will prove invaluable to the research worker.

"**Transmission.**—In an important paper that may throw some light on the problem of the transmission of kala-azar, Major R. Knowles, Dr. L. E. Napier and Assistant Surgeon R. O. A. Smith, I.M.D., reported that they had been able to show that flagellation of *Leishmania donovani* occurred in the gut of the sandfly, *Phlebotomus argentipes*. Out of 56 consecutively dissected laboratory-bred flies, fed three to five days previously on kala-azar patients, 25 flies showed flagellates in their fore- or mid-gut. Controls were carried out with 46 laboratory-bred flies fed on patients who were not suffering from kala-azar and 407 wild flies were dissected, all with negative results.

"**Bed-bug experiments:**—Major H. E. Shortt and S. C. Swaminath infected a mouse with *Leishmania* by injecting into its peritoneal cavity the contents of the gut of a bed-bug, *Cimex hemiptera*, which had previously fed on the peripheral blood of a kala-azar patient. In another paper they showed that the flagellate forms of *L. donovani* lived longer and with more certainty in the gut of *Cimex lectularius* than in the gut of *Cimex hemiptera*. This is an interesting observation in view of the fact that *C. hemiptera* and not *C. lectularius* is the bed-bug that is found in the endemic area in Assam. The same workers report the occasional finding of *Nosema adiei* Christophers (1922) in the salivary glands, the gut and ovaries of *C. hemiptera*; they give a few notes on the life history of this parasite.

"**Diagnosis.**—Lieutenant-Colonel F. F. Elwes, Drs. V. K. Narayana Menon and P. S. Rama Krishnan suggested that—although useful—the 'aldehyde reaction' in kala-azar was by no means a wholly reliable test and reported that in 23 per cent. of proved cases of kala-azar they had found the reaction negative, whereas a certain number of clinically suggestive cases which had given a 'negative' liver puncture gave a positive 'aldehyde reaction'; these latter cases improved on antimony treatment. In reply to this paper Dr. Napier pointed out that in the early stages of the disease the reaction was always negative, but that he had had no experience of cases other than kala-azar cases giving a really positive 'aldehyde reaction.' He suggested that liver puncture without culture was not a reliable method of diagnosis.

"Major Knowles and temporary Assistant Surgeon B. M. Das Gupta described a very valuable method of diagnosis by thick film examination of the peripheral blood and claimed 67 per cent. of positive findings in kala-azar cases. The method is also useful in the diagnosis of malaria.

"Major Shortt discussed the relative value of the various diagnostic methods and their application as criteria of cure. He made the interesting observation that occasionally a case still showing parasites in the spleen pulp would become 'sterilised' in the course of time without further treatment. Dr. Napier reported a case where this had occurred and other case in which a transient infection had become cured without any treatment whatsoever. Two similar cases were reported by Major Knowles and Das Gupta in a paper on transient leishmaniasis in animals and man.

"**Treatment.**—'Urea-stibamine':—During the year several papers were contributed on the treatment of kala-azar with this drug; Dr. P. Foster reported 20 cases from a tea garden in Assam; Major Shortt and Assistant Surgeon R. T. Sen reported 20 cases treated in Shillong; Dr. U. N. Brahmachari reported 8 'resistant' cases and 11 other cases treated in Calcutta, and finally Dr. J. Dodds Price reported 8 'resistant' cases treated at Salona. The vast superiority of this drug over the ordinary tartrates in the treatment of kala-azar is shown by all these papers; the testimony of Dr. Dodds Price with his long experience of the disease is perhaps the most valuable. He concludes his paper with the following words:—"I am of the opinion that urea-stibamine is a most valuable remedy

in the resistant type of the disease.....I have treated fifteen cases of kala-azar that had had no other form of treatment previously, but, although these cases have done well, my results have not been so striking as in the resistant type of the disease and I have had no dramatic cures after only 5 or 6 injections; the average number working out at 14.'

"Drs. Brahmachari and Das in further experiments on the chemical constitution of 'urea-stibamine' have concluded that this has to be modified, and that the compound is not the urea salt of para-amino-phenyl stibinic acid, as was originally suggested by the senior writer. They also showed that unlike 'stibamine' this compound does not undergo polymerization. The same writers, working in conjunction with Drs. S. C. Choudhury and P. B. Sen, have shown that when sodium antimony tartrate is injected intravenously 6 per cent. of the antimony is excreted by the kidneys in the first 24 hours, but when 'urea-stibamine' is used 30 to 40 per cent. is excreted in the same period; they suggest that this accounts for the low toxicity of the latter drug. They also showed that antimony could be demonstrated in the urine two months after a single dose of antimony tartrate, and that only a small quantity of antimony was excreted in the faeces. In further researches on the excretion of antimony Drs. Brahmachari and Sen have concluded that there is a maximum concentration limit in the tissues of the body which acts as a safeguard against accumulation of antimony in the body.

"Sodium and potassium antimony tartrate:—Dr. Napier in a paper on the problem of confirming a cure, attempted to lay down a rule of dosage which would be useful to workers away from laboratory conveniences. His conclusions were based on an analysis of 95 hospital treated cases whose treatment had been controlled by spleen or liver puncture and whose subsequent history had been ascertained. He concluded that 4 grammes of either sodium or potassium antimony tartrate per 100 lbs. body weight of patient was necessary to ensure a cure in all but definitely 'resistant' cases, but that this maximum dosage could be modified in certain cases; he suggested a definite rule for these modifications. He concluded that there was no definite rule that could be made for 'resistant' cases, which he suggested formed about 5 per cent. of the total cases coming for treatment.

"Dr. A. Mukerji suggested that the reactions which occasionally occur with watery solutions of sodium antimony tartrate could be avoided by the use of saline solutions of the tartrate.

"The Director of Public Health, Assam, reports that during the year 1923 no less than 35,071 cases of kala-azar were treated in the province with a death rate of 11.7 per cent., and that up to the end of August 1924, 37,112 cases had been treated as compared to 24,592 for the same period last year. He does not attribute this increase to an increase in the disease but to the greater facilities offered to the patients and to their increased willingness to take advantage of these facilities.

"At the Calcutta School of Tropical Medicine trial is being made on a large series of cases with meta-chloro-para-acetyl-amino-phenyl stibiate of sodium (von Heyden 471) and with 'Stibamine glucoside,' and at the Pasteur Institute, Shillong, a comparative trial of the above-mentioned two compounds and 'urea-stibamine' is being carried out.

"Pathology and laboratory technique.—Dr. M. N. De described a useful method of staining tissues to demonstrate the intra-cellular position of the parasites.

"A method of estimating the globulins in serum was described by Dr. C. B. Ray. He found that the increase in the globulin content of kala-azar patients' serum was due to an increase in the euglobulin fraction, which showed an increase from the normal of 7 or 8 per cent. to 40 or 50 per cent. of the total globulins. He suggested that the various serum tests for kala-azar depended on this fact.

"Captain P. Ganguli (T.C.) reported the presence of occult blood in the stools of practically every kala-azar case that he examined and he also noted that the specific gravity of the blood of kala-azar patients was always below 1,050.

"Dr. Napier reported that the hydrogen-ion concentration of the blood was very little changed in kala-azar patients, but that the power of neutralising both acid and alkali, i.e., the buffer power, was markedly reduced. He described a modified colorimetric method of estimating the pH of the blood and other coloured fluids. In another paper the same writer described a method and gave graphs for the preparation of N.N.N. medium of various concentrations of the hydrogen-ion, and in a third paper written in conjunction with Dr. P. Murugesan he reported that the pH range at which the flagellate stage of *L. donovani* could remain viable was from pH 4.75 to pH 8.38. They showed that the flagellate developed from the round form much more rapidly in medium slightly to the acid side of normal, and suggested that with this wide range of viability the flagellate might pass through the stomachs of people suffering from a slight degree of achlorhydria and of infants."

Helminthic Diseases.

Dr. Asa C. Chandler reviews the year as follows:—

"A number of valuable pieces of work in the field of helminthology have appeared; they may best be reviewed under the heads of ankylostomiasis, dracontiasis and filariasis, flukes and tapeworms, and anthelmintics.

Ankylostomiasis.—The complete report of the ankylostomiasis inquiry in Madras by Dr. K. S. Mhaskar (*Indian Med. Res. Memoirs*) is the outstanding publication of the year in this field. The report covers eight years' work in the Madras Presidency, and contains the results of much valuable survey and experimental investigation. All of the results have previously appeared in a series of 45 papers, but this incorporation into a single memoir adds greatly to their practical value. In new work published within the year, Mhaskar (*Indian J. Med. Res.*) has called attention to the rapid diminution of hookworm larvæ in night-soil. Dr. G. C. Ramsay (*Indian Med. Gaz.*) questions Dr. McVail's suggestion that the high temperature of a pig's body (104°F.) is injurious to human hookworm eggs passed through its digestive tract, and points out that viable hookworm larvæ can be obtained from febrile patients. The whole question of the significance of animals as disseminators of human helminthic infections was investigated by Dr. A. C. Chandler (*Indian Med. Gaz.*) who called attention to three methods of dissemination by animals; (1) as hosts; (2) by mechanical transfer of eggs on feet and body; and (3) by ingestion of faeces and subsequent passage of undamaged eggs. Pigs harbour a *Necator* which may be a mere hostal variety of the human species, but various attempts to infect pigs with larvæ of human origin have failed. The passage of eggs unharmed through the digestive tracts of pigs, dogs and rats was proved, viable eggs being passed in the faeces of these animals for at least 72 hours after an infective feed. The danger of allowing coprophagous animals to have access to human faeces is emphasised. Dr. L. F. Hirst (*Ceylon J. Science, Med. Section*) has discussed available methods of isolating nematode larvæ from soil, sludge and sewage, and has described a modification of the Baermann technique for isolating larvæ from gasified effluents and sludges; he also describes methods of separating infective nematode larvæ from soil nematodes by their aerial extension on soil surfaces, penetration through porous membranes into warm solutions, and their ability to penetrate the skin and reach the lung of the rat. Experiments were carried out on viability of hookworm larvæ in different types of soil which showed that in a Ceylon laboratory in the cool season larvæ could survive for four months, and in fair numbers for two months; at 37°C. they died much more rapidly. Mention should also be made of an important piece of work on mass

diagnosis of hookworm infestation by Lieutenant-Colonel Clayton Lane (*Trans. Roy. Soc. Trop. Med.*), for although no longer in India, his long and fruitful service here has given India an undying interest and sense of partisanship in his work. Lane has described a method of direct centrifugal floatation for the detection of hookworm eggs in faeces which is very ingenious, effective and very practicable if the simple though special apparatus necessary is at hand.

Dracontiasis and Filariasis.—A very thorough and highly valuable piece of work on dracontiasis has been published by Dr. N. H. Fairley and Lieutenant-Colonel W. G. Liston in a series of six parts (parts 1 to 5, *Indian Jl. Med. Res.*, part 6, *Indian Med. Gaz.*). In part I, three etiological factors in the disease are considered,—the female worm, the embryos, and secondary bacterial invaders. Evidence is adduced to show that the female worm injects a toxic substance into the subdermal tissues which results in the formation of the blister, and by absorption causes the early systemic symptoms such as urticaria, cyanosis, dyspnoea, gastro-intestinal disorders, giddiness, etc. The development of the ulcer and structural relation of the worm to it is accurately described. The only lesions produced by the embryos are subacute sterile abscesses; bacterial invaders are responsible for all septic complications. Part II deals with the effect of digestive juices on Cyclops and guinea-worm larvæ. Attempts to infect monkeys were negative. Part III contains an account of local Indian remedies, the most interesting of which are the time-honoured custom of douching and winding, and a method of extraction by suction. Part IV describes the clinical picture, including systemic toxic symptoms, the location of the ulcer (on the lower extremities in 86.5 per cent. of cases), and the blood picture. Part V discusses intravenous medication. It is pointed out that if septic complications have developed, immediate mechanical extraction is necessary whether the worm is dead or alive; without sepsis, intravenous medication which was lethal to the worms would be valuable if such a medication could be discovered. Tartar emetic is of no use. Part VI deals with the general subject of treatment, which varies according to the pathological condition and state of the ulcer, especially with respect to the presence or absence of sepsis. Previous to blister formation, rupture of the parasite is likely to be followed by urticaria erythema, etc. If the blister is present it should be aspirated aseptically in order to limit the size of the subsequent ulcer; if ruptured, the prevention of sepsis is of prime importance. If the worm is closely convoluted it is best excised *en masse*, otherwise mechanical extraction by intermittent traction and massage toward the sinus is advised, the technique is carefully described. A new operative technique is also described by which the worms can be removed in sections with excellent results; 13 of 19 cases were cured within a week. Local antiseptics and narcotic injections are of no use, and there is danger of chemical inflammation of the tissues. Adrenalin is valuable in relieving urticaria, asthma, etc., which herald the appearance of the adult worm in the subcutaneous tissues. Major R. E. Wright (*Indian Med. Gaz.*) has described a case of an encysted guinea-worm under the eyelid and upper orbital boundary in a child of 5, removed by operation; the worm was identified by Prof. Leiper at the London School of Tropical Medicine.

On the subject of filariasis very little has been published during the year. Dr. V. T. Korké (*Indian Jl. Med. Res.*) has described a new species of microfilaria from a dog, and gives a detailed description of *Spirocerca sanguinolenta* of the dog, calling attention to its generic affinities. Dr. A. C. Chandler (*Parasitology*) has described several new species of adult and embryonic filariæ from Indian birds. Human filariasis has been entirely neglected in Indian publications.

Flukes and Tapeworms.—Dr. N. H. Fairley (*Indian Med. Gaz.*) has made some experimental studies in intravenous therapy on goats artificially infected with

Schistosoma spindalis. Of 19 animals treated with tartar emetic, a complete cure was obtained in only 5; in 3 the parasitic level was reduced; and in 11 the treatment was a failure. Urea stibamine failed in all of 6 cases. Emetine hydrochloride proved to be an absolutely specific cure in all of 5 cases. The drug has a lethal action on the adults in the portal system, the worms filtering out into the portal vessels, where they set up a secondary thrombosis before their final disintegration by phagocytosis. Ova in the tissues diminish progressively, disappearing after a few months; living ova disappear rapidly. Pathological lesions disappear with the death of the worms. Mr. R. B. Lal (*Indian Med. Gaz.*) has shown that cases of *Schistosoma hamatobium* are sometimes positive to the aldehyde reaction, thus making the value of this test doubtful where schistosomiasis and kala-azar occur together. Lieutenant-Colonel Clayton Lane (*Annals Trop. Med. and Parasit.*) has discussed the morphology and systematic position of *Gastrodiscus hominis* and he concludes that the grounds for its separation into a separate genus, *Gastrodiscoides*, are untenable. Mr. G. D. Bhalerao (*Annals Trop. Med. and Parasit.*) has made a study of the trematode parasites of the food mammals of Rangoon, in which two new species were described. Dr. M. B. Soparkar (*Indian Jl. Med. Res.*) has described a new cercaria from northern India.

Prof. F. J. Meggitt (*Parasitology*) has published a valuable article on the collection and preservation of tapeworms. He has also done some interesting systematic work on cestodes, including an account of the tapeworms of the mongoose (*Parasitology*) and of pigeons in Burma (*Parasitology*), with descriptions of several new species; a description of a new tapeworm from a duck (*Annals and Magazine of Natural History*); and an account of *Ligula ranarum* in a frog in Rangoon (*Annals and Magazine of Natural History*). Meggitt has also made a contribution to the life history of a reptilian tapeworm (*Annals Trop. Med. and Parasit.*). Major F. J. W. Porter, R.A.M.C. (ret.) (*Indian Med. Gaz.*) has described a remarkable case of hydatid of the liver of 20 years' duration. The cyst was enormous and burrowed down into the pelvis between the parietal peritoneum and the abdominal parietes; the case simulated chronic tubercular ascites and peritonitis. Washing of the cavity after drainage with pure hydrogen peroxide, and later zinc ionization, effected a cure in a few weeks.

Anthelmintics.—Dr. K. S. Mhaskar (*Indian Jl. Med. Res.*) has studied the inhibiting effect of anthelmintics on the eggs of hookworms and roundworms, and found that beta-naphthol, thymol, carbon tetrachloride and santonin have a fleeting effect lasting only three days, whereas oil of chenopodium may suppress ovulation for as long as 12 days. Post-treatment examinations, therefore, should be made after a lapse of 3 or 12 days according to the anthelmintic used. Drs. J. P. Bose and A. K. Mukerji (*Indian Med. Gaz.*) investigated the effect of carbon tetrachloride on liver function in uncomplicated ankylostomiasis cases given 70 minims of CCl₄ and one oz. of saturated solution of magnesium sulphate on two consecutive days, by means of the levulose tolerance test; they found no evidence of any functional disturbance. Major R. N. Chopra and Dr. A. C. Chandler made a study of Indian santonin prepared from *Artemisia maritima*, indigenous in Kashmir, as an anthelmintic, and found that it was fully as effective in expelling *Ascaris* as the ordinary European drug; they point out that santonin is still our most effective ascaricide, though very expensive."

Leprosy.

Dr. E. Muir reviews the year as follows:—

1. "**Epidemiology.**—Incubation period. This most difficult and obscure subject has been dealt with in a masterly article by Sir Leonard Rogers.

He analyses the figures available from Hawaii and the Philippines and shows from these and other statistics

that the length of the incubation period varies with the length and closeness of contact. Under conditions of close contact, as when a child is in the arms of a strongly infectious mother or when there is direct inoculation, the period may be as short as 6 months; where infection is due to sleeping on the same bed with a leper the average period is 20 months; where the communication is not so direct, as where the person affected has lived in the same house with a leper, the average period is 3 years.

There are other factors which are not mentioned in the paper which must be of no less importance. Thus the stage of the disease of the infecting leper, and the number of bacilli in his skin and mucous membranes, and the presence of predisposing or accompanying diseases such as malaria or syphilis, must have a very marked effect on the length of the incubation period.

The length of the apparent incubation period must vary very much with the intelligence and power of observation of the patient, as in one case two small anæsthetic patches had remained constant for 22 years as the only sign of infection; a thickened great auricular nerve was also found when the patient was examined, making the diagnosis certain.

2. Communicability. The hygienic conditions under which the community lives must always be the most important factor with regard to the communication of leprosy. Filthy habits, both personal and domiciliary, promiscuity, both general and sexual, are strong determining factors. 'Sir George Newman mentions the unrestrained sexual relationships in the middle ages in England as having favoured the increase of leprosy. Even in recent times in the province of Galicia in Spain the most unusual feature of a high leprosy rate among females was attributed by Tello to their promiscuous habits during the temporary emigration of their husbands.'

In the Croonian Lectures, Sir Leonard Rogers propounds an interesting hypothesis that 'infection by mild tubercle of a large proportion of a population may render it less susceptible to the infection of leprosy, this being one factor in the extinction of leprosy as an endemic disease in Western Europe, in addition to improved hygiene and other influences.' He gives statistics to show that the incidence of leprosy is to a certain extent in inverse ratio to the incidence of tuberculosis in many countries.

3. Predisposing causes. An important factor in the incidence of leprosy has been brought forward during the year, viz., that other concurrent or predisposing diseases bear a very important part in the incidence of leprosy. The disease cannot be communicated to the lower mammals, and it appears as if it will seldom develop in man unless there is some other disease present, or some other cause to lower the resistance of the body and render it a suitable soil for the growth of the leprosy germ. Among the most important of these diseases is syphilis, a very large proportion of positive Wassermann reactions being found in leprosy. Thorough anti-syphilitic treatment renders a large proportion of these negative and in such cases the appearance of the negative Wassermann is followed by marked improvement in the leprous symptoms.

Malaria, gastro-intestinal diseases, hookworm, and other debilitating diseases have also an important bearing on the incidence of leprosy.

Symptomatology.—The prolonged nature of leprosy has obscured the important fact that it is a self-healing disease, the course of which may be represented diagrammatically by a parabolic curve, with few bacilli and low immunity in the first stage and with many bacilli and little immunity in the second stage; during these two stages the curve is rising until finally on the descent of the curve the third stage is reached, one of increasing immunity, resolution and disappearance of lesions and bacilli, although this as a rule does not happen until deformity and crippling have been produced. The grossness of the infection as indicated by the height of

the curve above the base line is influenced by the degree of resistance to the invading organism. The less heavy the infection the more does the disease tend to be concentrated in the peripheral nerves, and the nerve (anæsthetic) type of leprosy is thus indicated by a flat curve. In the grosser skin (nodular) type the earliest and latest lesions (when the high curve is near the base line) are associated with nerve symptoms, viz., anæsthetic patches in the early stage and distal, trophic lesions in the late. A mild type of leprosy (indicated by a flat curve) may at any stage in its course be suddenly changed into a more virulent type by the lowering of resistance due to the contraction of some other disease, which would be indicated by an abrupt rise in the curve.

A curious condition found in the nerve type of leprosy is nerve abscess. These may be single or multiple; when the latter, they are generally confined to one nerve and may communicate with one another through a hollow lumen in the nerve trunk. A nodulation first occurs due to a granuloma formation; this becomes caseous and later liquid pus is formed. This pus is sterile and no acid-fast bacilli can be found in it. In the cases examined the disease was confined either to one nerve or to nerves of one limb, no trace of leprosy being found in other parts of the body. It would therefore appear as if the more severe the nerve lesion, the more is the disease limited in its extent.

Major J. Taylor and Captain Malone published an interesting paper on the complement fixation test in leprosy, using defatted tubercle bacilli as antigen. Positives were given in tubercular leprosy in 96 per cent. and in nerve and mixed cases in 92 per cent. 14 normal controls and 23 positive-Wassermann-reaction controls were all negative. Tuberculous controls gave 20 positive out of 30 cases tested.

Treatment.—1. The importance of early treatment in tuberculosis is generally recognised. In leprosy, however, a disease in which the early clinical signs are much more easily recognised than they are in tubercle, much more care has been expended on the later stages when disfigurement and disablement have started their ravages. Yet leprosy when taken early is much more amenable to treatment than is tuberculosis. The fact is that ignorance regarding the early symptoms of leprosy, fear of loss of employment, or social ostracism should the patient be known to be suffering from leprosy, and the fatalism which submits to the inevitable in a disease supposed to be incurable, all combine to keep the patient away from medical aid in the early stages. Yet there is evidence to show that almost all cases which come under treatment at the earliest stage at which they can be diagnosed clinically, and who are treated efficiently and for a sufficiently long period will lose all active signs of leprosy and will have a fair prospect of remaining free from the disease for the rest of their lives, provided they are able to maintain their general resistance at a reasonably high level. It is therefore highly important that clinics should be started to which patients can be attracted by the hope of cure and that doctors should be trained in the early signs of leprosy and the best remedies to be used.

2. The treatment of accompanying and predisposing diseases must necessarily take precedence of any special treatment that may be used. It is useless, for instance, to attempt any form of anti-leprotic treatment when a syphilitic infection co-exists, until the syphilis has first been eliminated by appropriate treatment.

3. While many forms of treatment have been tried, the various preparations of hydnocarpus and chaulmoogra oils are on the whole still the most popular. Of these the ethyl-esters are the most widely used. An improvement in the preparation of these esters has lately been adopted in Calcutta where undistilled esters prepared without boiling have been found more simple to manufacture, less painful on injection, and more efficient in action. The addition of creosote to the esters as used in Calcutta has been found in the Philippines to increase their efficiency.

Wilson of Korea has found the injection of pure chaulmoogra oil less painful and more efficient than the injection of esters. This has been confirmed in Calcutta, where as much as 12 c.c. of pure hydnocarpus oil has been injected subcutaneously by infiltration without any complaint of pain.

Wilson also gets good results with chaulmoogra oil given orally, and Travers of Kuala Lumpur advocates the oral administration of the powdered seeds of *Hydnocarpus anthelmintica* mixed with half the quantity of *Cannabis indica* seeds.

4. Any treatment is bound to fail which neglects the ordinary life and habits of the patient. It is being more and more realised that the old type of leper asylum where admission implies utter abandonment of hope, must be abandoned. The following is an extract from a report of the Kwanju Leper Institution in Korea which is being run on more modern and humane lines:— 'In the treatment of leprosy I feel that the hygienic measures are almost as important as the administration of drugs. Patients here are given baths twice weekly and all are encouraged, even the one-legged, to work in the garden. The regular work as a form of exercise is excellent for them, and in many patients the stiff joints are soon much better and the general condition is improved. One of our lepers has been trained to care for the teeth; scaling and cleaning is done and extractions performed. We have taught our lepers various kinds of industrial work, and they lead a very active life. Our buildings are erected by them and they make all the bricks. Many are carpenters, masons, shoemakers, tinkers, etc. They produce all the vegetables used, and every room is a garden club that must prepare its own pickles and sidedishes, so this practically forces the cripples to get out and do some gardening. The spirit of the place is good. All are cheerful, games are allowed, and on the whole they are unusually happy. Some of the lepers have been trained by various members of the hospital staff so that now they do practically all the medical work required for their own cases, including the mixing of drugs, giving of injections, performance of minor operations, etc., and they are well able to use the microscope.'

Tuberculosis.

Dr. Muir writes:—

"If other diseases have slain their thousands, tuberculosis has slain its tens of thousands. If malaria be recognised as the most fatal disease in the country districts of India, tuberculosis must be given precedence as regards fatality in the towns. The *Calcutta Medical Journal* in its editorial for July, 1924, quotes from the report of the Bengal Public Health Department and the report of the Calcutta Health Officer. There are grounds for believing that tuberculosis caused 100,000 deaths in Bengal during the year and that there were 2,216 deaths or 2.4 per thousand in Calcutta. The incidence of deaths from this disease varied in different wards, giving 5.4 per thousand in ward 20 and only a little over 0.2 per thousand in ward 3. It varied in different communities, being 3.2 among Mohammedans and only 2.2 among Hindus. It varied according to sex, 6 females dying for every male between the ages of 15 and 35.

The fact that bovine tuberculosis is not found in India does not mean that there is not a danger of this disease appearing in the future if due precautions are not taken. Its absence is mainly due to two causes, viz., the low breeding of the cattle and the open-air life, which most Indian cattle lead. It has been shown that the usual type of Indian cattle is not susceptible to bovine tuberculosis and that most cases of tuberculosis in Indian cattle are due to the human type. The late epidemic of bovine tuberculosis at the Bombay Zoological Gardens reported upon by Lieutenant-Colonel W. Glen Liston and Dr. Soparkar, where four spotted deer and a gazelle were found to be suffering from tuberculosis with characters of a bovine type, and an antelope, a spotted

deer and a llama gave cultures having many of the characteristics of bovine tuberculosis, shows that there is a distinct danger of infecting cattle in India through imported cattle. As breeding of cattle proceeds in India the danger of bovine tuberculosis becoming endemic in India is bound to increase and only careful prophylactic measures will insure its prevention. The epidemic in the Bombay Zoological Gardens is supposed to have been due to three llamas imported from Germany and it was only stopped by the slaughter of all suspected animals and other strict preventive measures.

Lieutenant-Colonel R. Row has prepared an antigen by subjecting tubercle bacilli to autolysis and then extracting with petroleum ether. He finds three layers, the topmost containing the lipid material which causes the acid-fastness in solution; the second, in the form of a soft, whitish cake is made up of agglutinated tubercle bacilli which have to a large extent lost their acid-fastness; the lowest layer consists of saline in which the autolysis had taken place. The upper layer produced no positive complement fixation and produced very severe local reactions both in guinea-pigs and in man. The second layer was feebly antigenic in complement fixation; guinea-pigs stood 5 mgm. subcutaneously and rabbits 2 mgms. intravenously; the treated guinea-pigs showed definite immunity when injected with virulent tubercle bacilli. This layer also showed distinct curative value in a controlled guinea-pig experiment, and in man it was distinctly beneficial both in glandular and pulmonary cases.

'It is an ill wind that blows nobody good,' and even tuberculosis seems to have its value. Sir Leonard Rogers in his Croonian lectures shows that there is a possibility that a widely spread light tubercular infection of the community such as exists in most Indian cities has a tendency to produce immunity to leprosy. It may be that tuberculosis as it spreads to the villages will help to stamp out the more dreaded though less fatal disease.

Though tuberculosis is certainly one of the four most fatal diseases of India, very little research work is being done in connection with it in this country as compared with many other less serious diseases. This is probably due to the feeling that so much research is being done in connection with tuberculosis in other countries. One line of investigation, however, might be profitably taken up, viz., the statistical survey of the disease in India. While the incidence of tuberculosis is steadily diminishing in European countries, there seems to be little doubt that it is increasing in India. Although some work has already been done along these lines, there is urgent need for further investigation."

Relapsing Fever.

The recrudescence of relapsing fever in Madras Presidency is arousing considerable attention, and Major A. J. H. Russell, A. Ayyar and Captain Ubhaya (T.C.) contribute a study of the present situation. Norman Cheevers refers to a terrible epidemic fever which swept the Madras Presidency in 1824 and caused over 100,000 deaths, and which was possibly relapsing fever. Subsequent to that date, however, the disease appears to have disappeared locally, although Mysore State is suspected by the authors to have constituted a carry-over centre. Its recrudescence first drew attention in the Salem District in October, 1921. In 1922 it was epidemic in Tanjore, Trichingopoly and in Mysore. In 1923 it became fairly widespread throughout the Presidency, being chiefly confined to the rural areas, and to the *Pallans* and *Paraiyas*, the lowest of castes, living in mud huts. With regard to symptomatology of the disease, the authors note the existence of invariable jaundice, great and typhoid-like prostration, severe diarrhoea, and in convalescence marked alopecia, persistent jaundice, great emaciation, oedema of the feet and ankles, and above all susceptibility to attacks of intercurrent disease. The general death rate was 37 per cent., but in some villages as high as 66 per cent. As

regards age the incidence was chiefly in adults of 20 to 40 years, and females were more attacked than males—in contradistinction to what happens in the Punjab. The louse is incriminated on all grounds as the almost certain carrier. Dr. Turkhud reports that Assistant Surgeon K. V. Krishnan, in charge of an epidemiological unit, has worked on the disease in Ootacamund for nearly a year; serological and immunological studies have been undertaken to cover the several phases of the disease in experimentally infected animals, and a prophylactic vaccine is being prepared. It is hoped to carry these investigations forward and to publish their results in due course.

Major J. A. Sinton records the successful cultivation of the causal spirochæte in a modified Wright's tube, as first used by him for the cultivation of malarial parasites. The media used were either hydrocele fluid or horse serum, to each 100 c.c. of which $1\frac{1}{2}$ c.c. of 50 per cent. dextrose were added. Some of the cultures were still full of active spirochætes after six weeks.

K. V. Raju records an outbreak in October 1923 on the M. and S. M. Railway at Hubli. Male adults of low caste were chiefly affected. High fever, pains in the bones and joints, a staggering gait, and jaundice of more or less marked degree are the chief symptoms noted. Treatment with novarsenobillon was very successful.

B. K. Mehta records an interesting case of rat-bite fever, probably contracted in Bombay, with a typical temperature chart, successfully treated with sulfarsenol.

Diabetes.

The history of the work on insulin during 1924 is exceedingly instructive. In January, Major J. Taylor and Dr. A. R. J. Douglas published a paper on the (apparent) deterioration of insulin in India under tropical conditions of climate. With insulin locally purchased in Rangoon they obtained but a slight reduction in the blood sugar of rabbits with a dose of 10 supposed units, and none at all with 25 units from a second phial. A second sample was purchased from Calcutta, and of this 25 units proved to be scarcely potent at all. It was concluded that transit or storage under tropical climatic conditions might destroy the potency of insulin. In the same month, Major T. A. Hughes stated that a sample received direct from London in August 1923, and tested in October, supposed to be of strength 20 units, only shewed 3 units.

This was followed in February by a letter from the British Drug Houses stating that their "A. B." brand of insulin remained still fully potent when heated to 95°C . for one month, and that rabbits who shewed a blood sugar content of 0.21 per cent. were quite unsuitable for test. As a precaution, however, they were now sending their insulin out to India in cold storage. Messrs. Burroughs and Wellcome also drew attention to the fact that their insulin was prepared by the picrate process, a process which according to Professor MacLeod enables the insulin to withstand boiling without losing potency.

In March, Major H. Stott at Lucknow reported on 12 cases of diabetes treated for six months with freshly imported insulin, approximately 2,000 units having been used in all. Urinary sugar tests appeared to indicate that within 8 months, including an Indian hot weather, samples had deteriorated from $12\frac{1}{2}$ ths to $1\frac{1}{12}$ th of their original potency; and were only some $3\frac{1}{40}$ ths of the original standard; this being confirmed by Major Taylor on experimental tests of the same samples on rabbits. Dr. J. P. Bose (Diabetes Research Scholar at the Calcutta School of Tropical Medicine), tested "A. B." brand insulin and reported that "it retained at least $1\frac{1}{4}$ th of its original potency," and found that the same results held good whether the insulin was imported in cold storage or not. Burroughs, Wellcome insulin yielded somewhat similar results. Major Taylor in the meantime tested insulin sent out direct from London

to Rangoon in cold storage and found it to be fully potent, but was puzzled about the curious irregularities which occurred among his experimental rabbits. He concluded that rabbits whose blood sugar exceeded 0.12 per cent. should not be used, and they must be starved for 24 hours before testing. The British Drug Houses meantime examined a half-empty phial, reported defective by Dr. Bose, and returned from Calcutta to London, and found it fully active, although it had been exposed to tropical conditions for $2\frac{1}{2}$ months. Either, Dr. Bose concluded, the rabbit test is unsuitable under Indian conditions, or there must be some factor—not necessarily heat—present under tropical conditions which causes deterioration. At this stage, in an editorial note, we advised importation and keeping of insulin in cold storage. Fortunately the Indian Research Fund Association now took up the problem.

In May, Major T. A. Hughes reported that a sample of "A. B." insulin, bought in November 1923, and tested in January 1924, kept in cold storage, was fully potent on testing on rabbits. In July, Major Acton and Dr. Bose drew attention to the extraordinary differences in response to insulin given by rabbits of different colours. Given the same dose of insulin, albino rabbits might be almost unaffected, whereas black and white piebald rabbits got hypoglycæmia and convulsions. Small doses of adrenalin counteract the effect of insulin by causing hyperglycæmia, and even such factors as fright and exercise might affect the adrenalin content in rabbits. Colour variation and response is closely correlated with the adrenalin content of the animal.

Finally in our issue for last December, Major Taylor shews that the only permissible method of testing insulin under tropical conditions is to adopt MacLeod and Orr's standard method of test. Rabbits are selected whose blood sugar does not exceed 0.12 per cent., and are starved for 24 hours. A large batch is then injected with 0.75 to 0.125 c.c. of the insulin sample, and results are assessed in terms of insulin units, according to MacLeod and Orr's standards, any rabbit which departs markedly from the mean being discarded. The result is to give a standard assay, and under such conditions one insulin sample in tablet form and two in solution have proved to be of full potency; "although there is a variation in the response of Indian rabbits of mixed breeds, the average result from a series can be relied upon."

S. C. Sen Gupta draws attention to the relationship of diabetes to life insurance of Bengali subjects. All such cases are not unacceptable, and the glucose tolerance test is of value in selecting suitable cases for insurance; some other cases may perhaps be accepted at an extra premium. There is considerable need for further investigation on the subject.

Dr. J. P. Bose gives an account of a case of renal glycosuria in an Anglo-Indian female, 42 years of age. Her two brothers both shewed traces of sugar in the urine. The disease is usually hereditary and familial and is perfectly harmless, being due to the fact that the renal threshold for sugar excretion is lowered. It can only be differentiated from true diabetes mellitus by the glucose tolerance test. Such cases should be left alone.

"Deficiency" Diseases: Beriberi, Epidemic Dropsy.

The trend of recent work is to regard such diseases as food intoxication diseases, rather than as diseases due to deficiency of vitamins. Lieutenant-Colonel J. W. D. Megaw and Dr. S. P. Bhattacharjee contribute a study of a Calcutta outbreak of epidemic dropsy in 1923, in which lady medical students at the Campbell Medical School were chiefly affected. 70 cases are recorded and analysed; the chief symptoms being slight intermittent fever, the knee-jerks variable, no cardiac dilatation, and a distinctly raised blood pressure. A study of the diets concerned shewed no appreciable deficiency of any particular vitamin or other essential element; the distribution of the cases with reference to the rice

Wilson of Korea has found the injection of pure chaulmoogra oil less painful and more efficient than the injection of esters. This has been confirmed in Calcutta, where as much as 12 c.c. of pure hydnocarpus oil has been injected subcutaneously by infiltration without any complaint of pain.

Wilson also gets good results with chaulmoogra oil given orally, and Travers of Kuala Lumpur advocates the oral administration of the powdered seeds of *Hydnocarpus anthelmintica* mixed with half the quantity of *Cannabis indica* seeds.

4. Any treatment is bound to fail which neglects the ordinary life and habits of the patient. It is being more and more realised that the old type of leper asylum where admission implies utter abandonment of hope, must be abandoned. The following is an extract from a report of the Kwanju Leper Institution in Korea which is being run on more modern and humane lines:— 'In the treatment of leprosy I feel that the hygienic measures are almost as important as the administration of drugs. Patients here are given baths twice weekly and all are encouraged, even the one-legged, to work in the garden. The regular work as a form of exercise is excellent for them, and in many patients the stiff joints are soon much better and the general condition is improved. One of our lepers has been trained to care for the teeth; scaling and cleaning is done and extractions performed. We have taught our lepers various kinds of industrial work, and they lead a very active life. Our buildings are erected by them and they make all the bricks. Many are carpenters, masons, shoemakers, tinkers, etc. They produce all the vegetables used, and every room is a garden club that must prepare its own pickles and sidedishes, so this practically forces the cripples to get out and do some gardening. The spirit of the place is good. All are cheerful, games are allowed, and on the whole they are unusually happy. Some of the lepers have been trained by various members of the hospital staff so that now they do practically all the medical work required for their own cases, including the mixing of drugs, giving of injections, performance of minor operations, etc., and they are well able to use the microscope.'

Tuberculosis.

Dr. Muir writes:—

"If other diseases have slain their thousands, tuberculosis has slain its tens of thousands. If malaria be recognised as the most fatal disease in the country districts of India, tuberculosis must be given precedence as regards fatality in the towns. The *Calcutta Medical Journal* in its editorial for July, 1924, quotes from the report of the Bengal Public Health Department and the report of the Calcutta Health Officer. The disease is usually hereditary and familial and is perfectly harmless, being due to the fact that the renal threshold for sugar excretion is lowered. It can only be differentiated from true diabetes mellitus by the glucose tolerance test. Such cases should be left alone.

"Deficiency" Diseases: Beriberi, Epidemic Dropsy.

The trend of recent work is to regard such diseases as food intoxication diseases, rather than as diseases due to deficiency of vitamins. Lieutenant-Colonel J. W. D. Megaw and Dr. S. P. Bhattacharjee contribute a study of a Calcutta outbreak of epidemic dropsy in 1923, in which lady medical students at the Campbell Medical School were chiefly affected. 70 cases are recorded and analysed; the chief symptoms being slight inter-tation, and a distinctly raised blood pressure. A study of the diets concerned shewed no appreciable deficiency of any particular vitamin or other essential element; the distribution of the cases with reference to the rice

dealers suggested food intoxication through diseased rice. S. L. Sarkar and S. K. Bannerji record a similar outbreak in Atrasia village in the Malda district; 3 families out of 13 living in the villages were affected, all of them of Mahomedan illiterate cultivator caste, whilst 4 consecutive houses in the village were infected. The habit of chewing raw rice is incriminated as a possible cause; 6 cases occurred in one household which used to buy their rice supply two maunds at a time, an 8 to 9 days' supply, whilst 2 further cases occurred in the next house among children who used to eat rice from the first house.

With regard to beriberi Dr. C. E. Cobb shews how rice control may stamp out the disease. In Malaya early in 1919 there was a shortage in rice supplies, and in July of that year Government took over control of the rice supplies in order to prevent profiteering. As a result the diet of the Chinese coolies became more mixed, the rice ration was reduced by a half, its place being taken by vegetables and sweet potatoes, and beriberi practically disappeared. The rice now eaten was of an inferior quality and but slightly milled. In 1921 Government control of the rice market ceased and beriberi has again become prevalent. It is suggested that the Chinese coolies should be encouraged to adopt a more mixed diet. Professor W. BurrIDGE analyses the causes of œdema, of which he recognises two varieties:— (a) the œdema of pressure, due to filtration lag, where the limb does not suffer any diminution of function; and (b) the œdema of function, where the fatigued muscles have a higher osmotic pressure than normal and take up more fluid than normal; it is this œdema which is probably concerned in the œdema of beriberi and peripheral neuritis type.

Lieutenant-Colonel R. McCarrison reviews the relationship of rice to beriberi in a paper read before the Royal Society of Medicine (Tropical Diseases' Section). Beriberi is prevalent on the east coast of India, but absent from the west coast, yet parboiled and milled rice is eaten equally on both sides of India. Presumably, therefore, there are other factors in the ætiology of beriberi in addition to a diet of decorticated rice. The spread of beriberi has not kept pace with the extension of rice mills. Endemic beriberi has prevailed in Madras Presidency for at least a century and occurs among eaters of house-pounded rice, and among Pariahs who live on a mixed diet. The polyneuritis produced in pigeons by an exclusive diet of polished rice differs from beriberi of man. Colonel McCarrison has produced no less than four beriberi-like diseases in pigeons by feeding on a rice diet: (a) infective polyneuritis, due to infection, but favoured in its genesis by vitamine deficiency; (b) polyneuritis due to vitamine deficiency alone; (c) polyneuritis due to vitamine deficiency, but precipitated in its onset by various infections; (d) a malady resembling true beriberi, but due to an unknown agent acting in association with an insufficient supply of vitamines. In conclusion, there appears to be some association between beriberi and site or local infection.

The same author has also investigated the relationship of manure to the nutritive and vitamine value of certain grains. The problems concerned are very complex; but natural manures in general improve the vitamine and nutritive value of the grain more than do artificial manures. "Farmyard manure does something which artificial manures do not" and it would seem that part of this "something" is to increase both the nutritive and vitamine B value of the grain grown on soils fertilized by it.

Lieutenant-Colonel R. McCarrison also continues and concludes his studies of amino-acids. The injection of certain amino-acids tends to retard growth, especially that of tryptophane, whereas histidine tends to first retard and then enhance growth, and also hastens the metamorphosis of tadpoles. All the amino-acids studied, except tryptophane, cause reduction in the size of the thyroid, whereas tryptophane causes increase in this gland; all however cause reduction in the number of

thyroid vesicles. Long continued injections of tyramine and histidine cause retarded growth, reduction in the size of the thymus, and in the size or weight of the thyroid, pancreas, lungs and kidneys, together with a fall in the respiration rate for the first 35 days of administration. Tyramine causes a marked reduction in the size of the spleen, but histamine does not; histamine causes a marked reduction in the size of the heart, tyramine does not.

Colonel McCarrison's researches have been financed by the Indian Research Fund Association. In addition to his work on beriberi and goitre, he has studied the effects of certain amines and amino-acids on the animal organism, and of excess of calcium, iodine, proteins and sugar on the thyroid gland.

A. Swarup reports three interesting cases of poisoning by infected wheat. The symptoms shewn were vomiting, giddiness, weakness and a drowsy drunken stupor. The three patients concerned were an Indian doctor and two of his servants who had all partaken of the same wheat early in November within 3 days of one another. The flour made from the wheat was suspected and is at present under examination at the Calcutta School of Tropical Medicine.

Pneumonia.

Very interesting work has been carried out by Captain R. H. Malone on the types of pneumococcus prevalent in India. Lieutenant-Colonel F. P. Mackie reports as follows:—

"Five papers were published during the year in connection with an enquiry into pneumonia amongst Indian troops on the North-West Frontier. Two of them dealt with the solubility of the pneumococcus in bile and bile salt. The factors concerned in Neufeld's test were examined and the degree of solubility of pneumococci from various sources was estimated. It was found that pneumococci vary considerably in degree of solubility in 10 per cent. sodium taurocholate solution; that pathogenic strains and members of the fixed types I, II and III tend to be soluble, while strains from normal throats and of the type IV may be soluble or insoluble. Only 10 per cent. of the strains examined were partially soluble. The degree of solubility can be definitely expressed by comparison with a set of standard opacity tubes.

An examination of the types of pneumococcus prevalent in the Punjab and North-West Frontier showed the following distribution:—

	Per cent.
Type I	28
Type II	22
Type III	10
Type IV	40

Among the type IV strains, one fairly large sub-group constituted 25 per cent. of the 106 strains tested in all, and a second 9 per cent. of the total.

Similar work has been carried on at Guindy by Lieutenant-Colonel J. Cunningham, Major J. Cruickshank and Assistant Surgeon Ramakrishnan. 29 strains isolated from cases of lobar pneumonia were studied; and it was found that, with the exception of type I, the proportion of which is considerably higher, the other three types in Madras approximate to the figures given by Malone. None of the bile-insoluble cocci reacted with any of the type sera obtained from the New York State Health Department.

Finally Captain Malone prepared a vaccine of the types of pneumococci especially prevalent in the N. W. Frontier Province, and tested its value in the treatment of 66 cases. To be of value, he claims, the vaccine must be given early. He suggests that vaccine prepared from the peritoneal fluid of rabbits inoculated intraperitoneally with the sputum of lobar pneumonia cases may be better than that from cultures on artificial media. His figures are analysed by Major H. H. King, who concludes that the vaccine is effective in promoting

recovery, lessening the duration of the fever, and assisting the onset of crisis. It is useless after the 3rd day. Preparations have been made to treat cases of pneumonia in military hospitals throughout India this winter with a standard vaccine, and Major King's paper reviewing the recent work on lobar pneumonia was published in our December number to be of assistance to officers engaged upon this investigation. In pathological matters, indeed, recent years have seen an enormous improvement in military quarters, and progress is the order of the day. Lobar pneumonia is so important a disease in India that any agent of proved therapeutic value in the disease would be very welcome.

Asthma.

Dr. A. R. J. Douglas reports an interesting case of a young married woman so sensitive to horse emanation that she was compelled to give up riding. She was treated by desensitization by intradermal injections of horse serum, in doses rising from 0.01 to 1 c.c. and finally by intravenous injections. The treatment effected a complete cure, the patient being able to ride regularly without discomfort. Sensitization tests are now part and parcel of the daily routine in Major Acton's laboratory.

Typhus.

Two outbreaks of louse-borne typhus are recorded. The first, recorded by Major E. S. Phipson, occurred in Simla, 13 cases in all with the Weil Felix reaction strongly positive in the 12 cases examined, in 2 after convalescence, and as late as the 72nd day. He comments on the great value of the reaction in establishing the diagnosis, even after the patient has recovered. The second outbreak, recorded by Lieutenant-Colonel J. Cunningham and Assistant Surgeon J. H. Theodore, I.M.D., occurred in February-March among the Assam Rifles, when engaged in the Pituri operations in the Agency tracts of Madras,—8 cases with the Weil Felix reaction strongly positive in the 3 cases tested. The infection had previously been unknown in this territory, and was clearly imported from Assam. It is not known whether it has spread among the civil population, but no cases have been reported up to the present.

Lieutenant-Colonel J. W. D. Megaw discusses the typhus group of fevers, with special reference to Bhumi Tal fever, and McKechnie's study of it in 1923. He also records having personally contracted typhus after a bite from a tick, and records that Lieutenant-Colonel Chapman reports 3 further suspicious cases of tick-typhus in the Central Provinces. The author would divide up the group provisionally into louse-typhus, tick-typhus and mite-typhus until further knowledge of the methods of transmission is obtained. It is suggested that tick-typhus should be looked for in India.

Major-General Sir Patrick Hehir, I.M.S. (retd.), contributes a classical study of louse-typhus in Greek refugees, already reviewed in our columns. U. P. Basu describes 15 cases of suspected typhus in children between November 1922 and January 1923 in Calcutta; in 1 out of 3 where the Weil Felix reaction was tested it was positive at 1 in 30 dilution. The diagnosis seems a little doubtful. Captain A. F. W. da Costa describes 4 doubtful cases of spotted fever at Nagpur in July to November 1923, three of them being in the same family, and the Weil Felix reaction positive in the 3rd case at 1 in 25 dilution.

It is quite clear that our knowledge of typhus in India is still but fragmentary, and further information is badly wanted.

Small-pox.

There is but little to report, although the reports of different Directors of Public Health indicate that in some provinces, with slackening of legislation with regard to vaccination, small-pox is becoming an increasing menace. B. K. Mukerji describes a case of alarm; while Dr. J. E. L. Chinal is an advocate of

confection of sulphur internally, as sulphur is excreted through the skin, with or without the simultaneous administration of cream of tartar, and the external application of iodine and potassium permanganate.

Snake-Bite.

Jemadar C. Singh, I.M.D., reports a striking case of Echis bite. The patient, a male adult Pathan, was treated with hypertonic saline intravenously and his condition remained critical for 48 hours. Locally an incision was made and permanganate crystals rubbed in. Adrenalin and pituitrin were given hypodermically. The patient, after having received a lethal or almost lethal dose, recovered under careful treatment. Dr. S. L. McElderry complains of the necrosis and cellulitis following the hypodermic injection of gold chloride, and Major Clive Newcomb records an interesting case where a snake charmer offered for sale an "absolutely specific cure." One of his audience was so impressed that he permitted himself to be bitten by a cobra, and died in spite of the use of this and other remedies.

The Rev. Father J. F. Caius has continued his studies on antivenene. In conjunction with the Rev. Father A. Steichen, he has attempted to concentrate this serum. The percentage of water in normal serum was found to be greater than that in antivenene, but there is no correlation between the age of a serum and its concentration. The greater its age, the higher is its refractive index. From standards of refractivity it is not possible to distinguish between normal horse serum and antivenene, and the question as to whether the antivenomous principle has a real existence as a definite substance remains unanswered. Father Caius, Captain K. R. K. Iyengar and Major L. A. P. Anderson have also tried to concentrate anti-cobra serum. The antivenomous principle apparently exists in the serum partly free and partly associated with the globulin fraction. The potency of the serum is proportional to the amount of free antivenene in unit volume, and dilution increases the potency of the serum up to a certain limit. Increase of potency, however, is limited in one direction by the formation of an insoluble antivenene-globulin aggregate, and in the other by the dilution of the free antivenene.

Dengue.

Dengue appears to have been far less prevalent in India in 1924 than in 1923, and also to have been of a much milder type. A determined effort was made by Major Knowles and temporary Assistant Surgeon B. M. Das Gupta to incriminate a *Leptospira* as the causative agent of dengue, but ended in complete failure. *Leptospira*-like artefacts were repeatedly encountered in the blood of cases, cultures and inoculated animals, but nothing resembling a true spirochæte was seen. It is suggested that the *Leptospira* described in dengue by several different workers are of the nature of artefacts or that the cases in which the *Leptospira* were found were of another disease. An experimental trial at transmission by *Culex* mosquitoes failed.

Goitre.

In a lecture to the Ryde branch of the British Medical Association, Lieutenant-Colonel R. McCarrison sums up his well-known work on this disease. There are two main factors on which the prevention and cure of goitre depend: (a) the general hygiene of the individual, and especially of his intestinal tract; and (b) the amount of iodine available for the needs of the thyroid gland and of the organism generally. . . . In one case the hygiene of the bowel may be normal, but the intake of iodine in food and water be insufficient; this appears to be the case in sheep and other animals in certain parts of British Columbia. In a second the intake of iodine may be sufficient, but the state of the intestine is such that the available iodine or other constituent of thyroxin may not be made use of; this appears to be the case in many of the subjects of sporadic or toxic goitre so commonly seen in towns. In a third group

the amount of iodine may be relatively deficient in proportion to the other constituents of the food; in a fourth we may have a food poor in iodine, and continued infection of the bowel by polluted water, as in the endemic areas in the Himalayas. Further, constipation and imperfect drainage of the bowel may be as effective as a polluted water supply. The measures to be taken for the prevention and treatment of goitre are therefore clear.

Major M. A. Nicholson challenges Colonel McCarri-son's results at the Lawrence Military School, Sanawar, from the use of enteric vaccine in goitre. "Neither T. A. B. nor typhosus vaccine had any effect, curative or prophylactic, remote or near, on the endemic goitre prevalent at the school. Endemic goitre is a condition peculiarly liable to spontaneous disappearance and re-appearance in its endemic form among children. These fluctuations of the thyroid should be taken into consideration in judging the effect of any particular line of treatment. There are still many who regard the chemical composition of the drinking water as the essential factor in the causation of endemic goitre."

Nervous and Mental Diseases.

D. M. Vasavada records the apparent cure of 2 cases of epilepsy by intravenous administration of peptone, with considerable improvement in a third case. S. C. Mitra describes 7 cases of encephalitis lethargica as having occurred in Calcutta almost simultaneously in April-May 1924. The age distribution was from 5 to 30 years and 6 of the patients were females. The onset was with fever, headache, and vomiting; and the course of the disease characterised by lassitude, asthenia, delirium, difficulty in speech and deglutition, spasmodic twitchings, paralysis of accommodation and ptosis. Only one of the patients survived, and in this the gait was ataxic and the speech still not clear at the 6th week.

Major O. A. R. Berkeley-Hill and P. C. Das discuss the question of syphilis and mental disease in India. Syphilis is not more common among the insane than among the sane in India; rigorous anti-syphilitic treatment did not improve the mental state of the patients on whom it was tried, and syphilis—in contradistinction to what occurs in Europe—does not appear to be an important contributory factor to mental disease in India.

Lieutenant-Colonel A. W. Overbeck-Wright writes from Agra as follows:—

"Here we have been working on galvanism and endocrine preparations and our results with both are most promising, though as yet not in sufficient numbers to warrant publication. Galvanism I apply as I describe it on pp. 371-372 of 'Lunacy in India.' My results with my own private installation have been so uniformly good that I have now got an installation in the Asylum. It is very markedly sedative and in addition tonic and bracing as well, and its results in many cases seem really marvellous. Hebephrenia, mania, melancholia, neurasthenia, hysteria and similar conditions react to it rapidly and so far as I can judge permanently, but it is early days yet to dogmatise. Paranoia, G. P. I., katatonia and one or two similar conditions remain practically unaffected by it.

As regards endocrines, we seem to have practically eradicated status epilepticus from our causes of death by the prompt administration of pituitrin (1 c.c.) hypodermically so soon as symptoms threaten. Post-pituitary secretion has given excellent results in one or two cases of epileptic idiocy. Adrenalin hydrochloride also promised well in 1 or 2 cases of hebephrenia. On the whole, however, mixed preparations are the best. Carnrick's 'Hormotone' has given good results in some climacteric and senile cases, but on the whole I prefer the preparations of the Instituto Therapeutico Romano; their 'polyendocrine neurotonic tablets' for instance have given and are giving us excellent results in hebephrenia, paranoia, melancholia and other allied conditions. One has to continue for at least six months with

such cases before one can definitely pronounce the verdict, and as we have only begun this method of treatment this year, the utmost I feel warranted in saying from my own experience is that there seems to be great promise of immense benefit to be derived from endocrine treatment in many cases of mental and nervous disorders."

PHARMACOLOGY.

A number of papers of great interest were published from the department of Pharmacology, Calcutta School of Tropical Medicine.

Majors H. W. Acton and R. N. Chopra showed by a large amount of experimental work on animals that the phenomenon of susceptibility in different individuals depends to a large extent on the varying amounts of the endocrine secretions that are present in the tissues. The picture is that of a series of complex chemical interactions, where chemicals are aided or hindered by one another. The phenomenon known as idiosyncrasy, susceptibility, or sensitiveness according to these authors can be explained in this way. Drugs such as adrenalin, tyramin and pilocarpine produce entirely different effects on the blood pressure and respiration (bronchioles) of animals whose endocrine functions have been altered experimentally by extirpation of the thyroid or adrenals or by introducing large amounts of these secretions into the animals artificially. Idiosyncrasy of individuals to such drugs as quinine, or susceptibility to such diseases as beriberi, epidemic dropsy, etc., or sensitiveness of certain persons to the bases which produce urticaria, giant urticaria, asthma, etc., can be explained in this way. Major Chopra, Dr. Ghosh and P. De's observations on the toxicity of emetine are of interest to general practitioners. They sound a note of warning against giving a large number of injections of this drug to patients. By experiments on rabbits these authors have shown that emetine is a general protoplasmic poison having a selective action on the cells of certain organs. The parenchyma of the heart muscle is one of the earliest to be affected and this may account for the cardiac symptoms which sometimes occur during the course of injections.

The work of Majors Acton and Chopra on the local effects produced in the tissues by intramuscular injections is of practical interest in therapeutics. Antimony salts cause marked irritation and pain; emetine causes petechial hemorrhages and bruising; the salts of all the four main alkaloids of cinchona bark cause equally marked oedema, irritation and necrosis of the tissues.

Major Chopra and Dr. Asa Chandler have shown that santonin extracted from *Artemisia maritima* Linn (*A. brevifolia* Wall) which grows in the hill tracts of Kashmere State (Baltistan), closely resembles in its physical, chemical, and physiological properties the ordinary santonin. By trials on a series of cases they have shown that its therapeutic efficacy is just as good, if not better than that of imported santonin. If properly worked on a commercial scale, this santonin could be manufactured and sold very much more cheaply than the imported variety.

Major Chopra and P. De have shown that *Sassurea lappa* (kuth root) which grows abundantly in the mountains of Kashmere has three active principles, an essential oil, a glucoside and an alkaloid. These are pharmacologically active bodies and extracts made from the root diminish the number of attacks in bronchial asthma and reduce their severity and frequency. This drug is especially useful in cases of vagotonic origin, which form the majority of the cases in India.

Major Acton's paper on the vital processes that occur at cell surfaces is one of the most remarkable publications of the year. It is based on a large amount of experimental work done in conjunction with his colleague Major Chopra, and is of great pharmacological interest. Life processes essentially are rhythmic in character. They are conditioned by two main factors:—(1) Increase in electrical resistance at the cell surface which

causes a diminution in cell permeability, except to the inorganic salts which then ionise. (2) A diminution in electrical resistance with increased cell permeability, e.g., quinine is ten times as active at a pH of 6.0 as at a pH of 8.0 on *Paramoecium*. (3) Variations in permeability. Permeability is diminished by some organic substances, e.g., bile salts are antagonistic to and prevent the absorption of peptones and polypeptides from the gut. On the other hand some substances, such as electrolytes of inorganic salts, markedly diminish cell permeability to chemicals with large molecules. In living tissues a balance is struck. In dead tissues the permeability increases.

Another publication of pharmacological interest is one by Lieutenant-Colonel R. McCarrison who has shown that the action of adrenalin is usually favoured during the early stages of asphyxia, and disfavoured during the later stages. These effects of asphyxia on the action of adrenalin are due in the main to the gradually increasing carbon dioxide in the blood. The disfavoured effect of an excess of carbon dioxide on the action of adrenalin can be compensated for by increasing the concentration of adrenalin.

D. M. Vasavada advises 10 to 30 grains of sodium cocodylate intravenously in 5 c.c. of distilled water twice a week. He has seen good effects with this drug in cases of anemia, malarial cachexia, syphilis, psoriasis and sprue.

A pharmacological unit was established in connection with the Bombay Bacteriological Laboratory in charge of the Rev. Father Caius and Dr. Mhaskar. The Laboratory is well equipped and was opened for work on the 1st of June 1924. Work has been started on indigenous drugs and is already well advanced on *Holarrhiza antidysenterica* (kurchi) and *Butea frondosa* (polash).

A biochemical unit is also going to be opened in connection with the Bombay Bacteriological Laboratory.

SURGERY.

Major W. L. Harnett, F.R.C.S. (Eng.), writes:—

"It is pleasing to record that the output of surgical papers this year has been considerably greater than usual; many of them of a high order of merit and indicative of a spirit of progress and research. Surgeons in this country have tended in the past to confine themselves to stereotyped lines of work, content with an immense output of successful operations on conventional lines, and have shewn little disposition to embark on original investigations or to adventure into the more difficult fields, where exact scientific methods of diagnosis and elaborate technique are requisite. All this is changing, and with the improved equipment of the larger hospitals and the determination to make full use of modern methods, we may expect great progress in surgery in India in the near future."

Gastro-Intestinal.

Perhaps the subject which has aroused more attention than any other during the year is the question of the prevalence or otherwise of carcinoma and other surgical diseases of the intestine in Indians. Lieutenant-Colonel H. Halliday considers that among the hardy Sikhs and Pathans of the Punjab and N. W. Frontier Province such conditions as gastric and duodenal ulcer, appendicitis, cholecystitis, gall-stones, and carcinoma of the colon are very rare. On the other hand when the Indian becomes sophisticated and takes to European diets and customs, he may become the subject of intestinal stasis, appendicitis and carcinoma of the colon. As shewn in our editorial for last August, however, there appears to be a considerable difference of opinion on this subject among the authorities consulted, and much further information is wanted. The fine work being done in gastro-intestinal surgery by Lieutenant-Colonel E. W. C. Bradfield in Madras has been commented on in our columns. Colonel Bradfield shews that in Madras, at least, there is a wide field for such

surgery, and that, considering the emaciation and bad state of many of the patients dealt with, results are very good. He writes:—"As far as Madras is concerned, you have received the annual reports of the presidency hospitals, and I think they entirely disprove the idea that certain diseases such as cancer and surgical abdominal complaints do not occur amongst Indians. The trouble with most of our hospitals is that out-patients are generally seen and sent for admission by the least trained members of the staff, and that diseases which are not very obvious, or about which they have not been especially warned are usually missed.

I have asked my staff to put up a statement shewing the admissions for a few special diseases during the first 11 months of 1924. It shews that among 447 general major surgical operations for disease, 78 were cases of appendicitis, including 47 Hindus; 144 were duodenal ulcer, of whom 122 were Hindus; 23 were gastric ulcer, of whom 18 were Hindus; 12 were carcinoma of the stomach, including 8 Hindus; and 6 were carcinoma of the rectum, including 4 Hindus. Gastric and duodenal ulcers are very common, appendicitis not so rare as was formerly thought, while the more abdominal surgery we do, the more frequently are cases of gall-stones and their sequelae found. I think that dental infection is a very important predisposing cause.

I think the most marked advance in surgical treatment made in India during the last few years is in the treatment of abscess of the liver. Drainage has now been abandoned except in very rare cases, and the use of aspiration and emetine, which we owe to Sir Leonard Rogers, has reduced the mortality of this disease to practically nil."

The treatment of liver abscess is still inadequately dealt with in surgical text-books, and Sir Leonard Rogers' work and Lieutenant-Colonel Thurston's series of cases treated by aspiration have never received due recognition, and even recent works still advocate open operation. It is interesting to see that Colonel Thurston has again entered the lists in the columns of the *Lancet*, and that there is a revival of interest at home in this subject. Captain Sargood Fry's two cases of large liver abscesses which underwent absorption under emetine treatment alone, without aspiration, are of interest in this connection.

Drs. J. G. Martin and A. J. Jongewaard record an interesting case of a boy of 12 kicked in the abdomen by a horse, and admitted to hospital 8 hours later. There were almost no symptoms, and only slight local rigidity and a rising pulse rate indicated the necessity for laparotomy. Perforation of the jejunum was found, and the patient recovered after an end-to-end anastomosis. Dr. A. Bayley-de Castro records a case of strangulated diaphragmatic hernia of the entire stomach through an old stab wound into the left pleural cavity; the case proved fatal at operation. Captain J. B. Hance discusses the question of supernumerary spleen with reference to its causation and embryological significance, and records a case where the supernumerary spleen lay in the sac of a left inguinal hernia.

Calculus.

Lieutenant-Colonel A. J. Vernon Betts deals with litholapaxy and its limitations,—a most valuable paper which is the outcome of 20 years' experience. He advocates Weiss' lithotrites, and either an irrigator for washing out at a height of 2 feet above the bladder, or a special light type of evacuator made for him by Weiss & Co. The operation should be confined to those cases in which the stone can be easily grasped. The alternatives are median perineal lithotomy where the stone is just too big or too hard to be easily grasped or crushed; or suprapubic cystotomy for the residue of cases. His results are exceedingly good; 254 litholapaxies; 23 median perineal lithotomies; and 3 suprapubic operations; a total of 280 cases with only 6 deaths. K. S. Ranganathan records a case of vesical calculus with bilateral hydronephrosis, and R. M. Kar a case of vesical calculus associated with prolapse of the rectum.

Orthopedic Surgery.

An exceptionally interesting paper is that by Major W. L. Harnett on ankylosis of joints, shewing what a wide field there is in India for useful work in this class of surgery. Every Indian village and city swarms with cripples, yet given an enterprising and skilled surgeon and the co-operation of the patient very much can be done. In bony ankylosis it is often a mistake to do an arthroplasty; a sound ankylosis with a useful limb is often better practice. A very common cause of fibrous ankylosis in India is neglected gonorrhoea; physiotherapeutic methods, hot baths, paraffin baths, diathermy, massage and passive movements have a wide range of applicability here, but the most essential thing of all is to secure the patient's co-operation. Forced movement under anaesthesia to as great a degree as possible, followed by immobilisation in plaster of Paris is often very useful.

Lieutenant-Colonel C. A. Gourlay deals with two matters, anaesthesia and fractures. In connection with the first he pleads for more care and consideration in anaesthetising patients. Anxiety, fear and pain are all factors which go to increase shock in the patient. A preliminary injection of morphia and atropine will dull the senses before the patient is carried into the theatre; whilst the use of local infiltration or nerve block methods with local anaesthetics abolish shock, eliminate pain, and are of great value in reducing the amount of chloroform given to a safe level. There is much that can be done in operating theatres in India to reduce shock, which is too often neglected. In connection with fractures, x-rays should be used both before and after the fracture has been set and at frequent intervals subsequently; preservation of the vigour of the muscles and circulation by early movements from the outset is essential, also early restoration of functional utility by properly graduated exercises. Interesting figures are given for a series of compound fractures treated at the Sambhu Nath Pundit Hospital; of 39 consecutive cases 23 were cured, 8 were discharged otherwise and 8 died; "sepsis defeated us in 5 cases and 2 required amputation on account of long continued sepsis." These figures are capable of improvement. A compound fracture cannot be properly cleaned up without a general anaesthetic; restoration of bony deformity is a matter which there is no need to worry about until one is certain that all sepsis has been eliminated from the wound.

Antiseptics.

Major F. J. W. Porter, R.A.M.C. (retd.), advocates petrol for cleansing the skin prior to operation, as being both cheap and efficient, whilst Major A. H. Napier extols the virtues of electrolytic chlorine, "E. C." in surgical and midwifery practice. The skin at the site of operation is swabbed with pure E.C. the day before operation, and dressed with an E.C. compress of strength 1 drm. to the pint. It is again swabbed with pure E.C. before operation. A lotion of 1 drm. to the pint is used as a general antiseptic lotion. Cases are quoted of compound fractures practically converted into simple ones, of septic bone cases, carbuncles and cancrum oris rapidly yielding to E.C. treatment, and of its use in operations on tubercular glands of the neck.

Intravenous iodine has received considerable attention during the year. Lieutenant-Colonel W. W. Jeudwine states that thrombosis after its use is very rare, and he has only seen two severe cases of thrombosis in some 1,500 injections; it is probably not due to using the alcoholic tincture, but to local irritation of the intima of the vein at the spot where the iodine solution strikes it. Lieutenant-Colonel F. P. Connor records the routine use in his wards of intravenous iodine in septic cases ever since 1913, and has found it especially useful in cases of streptococcal infections and septicemia. He was first led to use it in connection with plague, and thinks that the results in plague are possibly encouraging. H. R. Wadhvani records its use in phlegmasia alba dolens, erysipelas, pelvic peritonitis, tubercular hip

disease, ischio-rectal abscess, in doses of $\frac{1}{2}$ to $1\frac{1}{2}$ c.c. of the tincture diluted with water and given at 3 to 5 day intervals; claiming very good results. Assistant Surgeon P. Bell, I.M.D., speaks of its value in pyæmia, recording a case where 4 injections and evacuation of pus from the hip was followed by rapid convalescence in a patient who was at first in a critical state. J. C. Chaudhuri claims to have used the method for some 6 or 7 years successfully in cases of cancrum oris, lobar pneumonia, enteric fevers, boils, carbuncles, and in pyrexia of uncertain origin with negative blood findings.

Carcinoma.

Dr. E. F. Neve contributes a valuable article on *kangri*-burn epithelioma. It is apparently due to chronic irritation by the heat of the *kangri*, the sequence of events being chronic dermatitis, epithelioma, sepsis, leading to the production of a foul and sloughing sore. The condition is evidence against the parasitic theory of cancer. The tumours are usually met with on the thigh or the lower part of the abdomen, and in advanced cases the deep femoral and even the external iliac glands may require removal. During the past 35 years at Srinagar, operations for *kangri*-burn cancer have averaged 45 a year. The technique adopted is to first remove the glands draining the area, and then deal with the cancer itself. It is often difficult to steer between the Scylla of imperfect removal and the Charybdis of excessive dissection in subcutaneous tissue, impairing the vitality of the thin skin of the groin or axilla.

K. S. Ranganathan records a case of what was apparently true primary carcinoma of the liver in an Indian coolie of 55; the diagnosis being confirmed pathologically. Major W. C. Paton records a case of carcinoma of the urethra in a Hindu male of 18, with retention of urine.

The question of betel-chewer's cancer has received some attention. Mr. R. L. Spittel contributes a striking photograph of a typical case to the *Lancet* and discusses the condition as met with in Ceylon. It is especially prevalent in Tamil women between the ages of 35 and 50. Also carcinoma of the tongue is not uncommon among them, whereas it is very rare in women in Europe. In a series of cancer cases at Colombo buccal cancer totalled 163 cases as against 137 of cancer of the rest of the digestive tract and only 13 of cancer of the breast. Histologically the condition is a typical epithelioma. Colonel Bradfield writes in this connection:—"The cancer of the cheek and jaw so common in South India is not due to the betel or tobacco which these people chew, but to the lime or *chumam* with which they are mixed. Samples of this lime contain 86 per cent. of carbonate of lime, and 50.3 per cent. of slaked lime and are very irritating."

General.

Major J. W. Barnett introduces a method of securing a high degree of local concentration of drugs in a limb by the use of a tourniquet and the intra-arterial injection of the drug. The drug must be alkaline or neutral in solution, must not cause coagulation of the blood and must not cause pain. Experimenting on cases of Madura foot he found that doses of sodium chloride up to 15 grains could be thus locally given with apparent improvement in the condition. He even suggests a technique for local concentration of drugs in the scalp areas, and considers that the method might be of value in local sepsis of the limbs and for the local administration of sera, e.g., of antivenene.

Two cases of *Rhinosporidium seceberi* infection are recorded; the first by T. S. Tirmurthi in a Malabar woman who had suffered for 20 years from this disease in the nose and had been operated upon 8 times; the second by Major W. L. Forsyth in a male patient aged 55 and coming from Calicut, where the left nostril, lacrymal sac and palpebral conjunctiva were all infected, and

the infected growths were suppurating. (As the recent and very fine studies of Professor Ashworth on this parasite shew, *Rhinosporidium seeberi* is not a protozoon at all, but a fungus of high order allied to the Schizosaccharomycetes.)

Gangosa has received some attention during the year. Dr. T. H. Holland records a striking case in Baluchistan, where yaws is unknown, in a male adult where, in addition to the nose being infected, the mouth was reduced to a tiny orifice. An operation to re-form the mouth was completely successful, and the Wassermann reaction was definitely positive. Lieutenant-Colonel J. R. J. Tyrrell recalls a similar case seen some years ago in Malwa, C. I., where the mouth was so much reduced that it would only just admit a goose-quill, and where re-formation of the nose and mouth were accomplished with success by operative procedures.

Assistant Surgeon J. Pereira records a case of local tetanus following on a wound of the dorsum of the foot, and cured by the administration of 4,500 units of antitoxin.

Major Harnett writes:—"Interesting and unusual surgical cases have been recorded during the year in great numbers. A. K. Ragavan records a successful case of drainage of a pancreatic cyst, and another of excision of a large lymphatic cyst of the neck. S. C. Das Gupta, L.M.S., records a case of abdominal injury successfully treated by resection and enterorrhaphy. Lieutenant-Colonel C. H. Reinhold, operating on a case of a large strangulated inguinal hernia, found himself unable to reduce the gut owing to the presence of a mass of caseating mesenteric glands in the ileo-cæcal angle; these were shelled out and the case did well. Space has allowed of only a few of the most remarkable cases being cited, but a special feature which we note with pleasure is the increasing number of surgical cases of interest which are recorded by Indian doctors in charge of small hospitals. Many of these operations would not be remarkable in a hospital in a large city, but when one considers the difficult conditions under which the work was done, the scanty equipment, the difficulty of sterilising dressings and appliances and the absence of trained anaesthetists and assistants, the successful issue of such cases reflects great credit on the operators."

Veneral Diseases.

Report after report, medical, surgical and ophthalmological draws attention to the enormous importance of venereal diseases in this country and to their very great prevalence. Much valuable work is being done by many official and unofficial and voluntary agencies, especially in the big cities of India, but the whole problem is so vast that decades must elapse before it is properly tackled. Propaganda and education are the only two remedies at present feasible.

Lieutenant-Colonel C. A. Gourlay, describing the work done at the Voluntary Venereal Diseases' Hospital for women at Alipore, comments on the unwillingness of patients to stay in hospital until cure is complete; they usually leave as soon as symptoms are relieved and can rarely be persuaded to undergo more than a month's treatment. A second important feature of the work is the great frequency of mixed infections; thus of 135 cases of soft sore, 98 also had syphilis, and 18 also had gonorrhœa. Acute gonorrhœa, which is a painless disease in the female, is rarely seen. In the usual chronic type of gonorrhœal case seen, the use is advocated of 5 per cent. picric acid in glycerine in a wool tampon for dealing with the cervical canal, which is the spot requiring most thorough treatment. Pustular syphilides, so rare in Europe, are very commonly seen in India, and may even be mistaken for small-pox. Finding that cases of arsenical poisoning were occurring after the use of the scheme of treatment recommended for army use by Harrison, he weighed all the patients, and found that their average weight was only 6 stone. Clearly a dose for a robust British soldier

of 10 stone was too large for a weakly Indian woman of 6 stone, and doses were accordingly reduced. The present scheme of treatment consists of four weekly injections of Stabilarisan, which Colonel Gourlay prefers to the other arsenical derivatives, and mercury inunction daily for one month. On leaving, the patient is given a further one month's supply of mercury ointment in the hopes that she will use it. Relapses are common; e.g., of 324 cases admitted in one series, 128 had previously been treated in the same hospital.

Dr. C. F. Chenoy advocates the treatment of syphilis with bismuth, using Neotrepol for preference in doses up to 4 c.c. by intramuscular injection. The results were good clinically in a series of cases; 9 illustrative cases are quoted. Major A. G. Tressider records a case of an unusual condyloma of the lower lip of a Marathi woman of 30, with a strongly positive Wassermann reaction, and M. L. Kundu two cases of progressive spinal paralysis in syphilitics undergoing treatment with 606. Such a condition, he believes, is *not* due to the treatment, but is not readily amenable to the usual routine anti-syphilitic treatment. The correct procedure is repeated lumbar puncture and intra-theccal injections of salvarsinised-serum. The cerebro-spinal fluid remains Wassermann positive, even after such repeated injections.

In the treatment of gonorrhœa, Assistant Surgeons J. R. Jacob and K. V. Verasingam advocate intravenous acriflavine, especially in early cases, where they have had rapidly successful results. The dosage recommended is 100 rising to 200 c.c. of a 1 in 500 solution, and 30 illustrative cases are quoted. If posterior urethritis is present, local measures are also necessary. Captain J. H. Barrett has introduced a new rod and guard electrode for ionisation of the urethra; a straight pattern for anterior urethritis and a curved one for posterior urethritis, with claims on account of its cheapness of construction and simplicity in use. Using zinc ionisation he records details of 35 cases treated, of which 29 were cured in from 3 to 12 applications, and in a period of from 7 to 40 days. Permanganate irrigations and hyoscyamus orally were used as adjuvants.

In this connection Major Harnett writes:—"The standards of cure adopted in some instances in such work are not sufficiently rigid. Many cases of gonorrhœa are of a mild type and the discharge quickly disappears under any treatment. It is not sufficient to say that gonococci are not found in the prostatic secretion. Repeated examinations, both microscopical and bacteriological, of the prostatic secretion after provocative injections, and a careful urethroscopic examination are necessary before such cases can be passed as cured. New methods of treating this disease are periodically brought forward, but all have so far broken down when tested by rigid scientific methods in institutions such as Rochester Row Hospital, where the cases can be followed up."

P. E. Pereira records the treatment of 69 cases of non-specific ulcer, with the Wassermann reaction negative, by 2 to 3 injections each of 2 to 3 c.c. of a 2 per cent. solution of tartar emetic, and claims that the method is worth trial.

HYGIENE AND PUBLIC HEALTH.

In a letter, the receipt of which we acknowledge with great pleasure on account of the authoritative status of its writer, Lieutenant-Colonel J. D. Graham, Public Health Commissioner with the Government of India, writes as follows concerning the general situation with regard to public health work in India:—"There is little to add to the situation so well described in your last year's report as reproduced from Colonel King's article in *Science Progress*.

Provincial autonomy in public health and sanitation has removed from the immediate sphere of the Public Health Commissioner with the Government of India much that formerly had to emanate from Simla or Delhi. The duties and responsibilities of the Central authority

will, I feel sure, gradually crystallise. Already international, national and inter-provincial matters in regard to public health, quarantine, the control of major ports, control of pilgrim traffic ex-India, control of emigration and immigration are definitely regarded as Central. The rapidly augmenting activities of the Health Committee of the League of Nations, and of the Bureau International in regard to health conditions in Asia generally must tend to centralise the disposal of such questions as arise, and this is in the nature of things a first step towards the establishment of such a central authority as is now considered necessary by most Federal States. The recent Port Administration Conference which, *inter alia*, had to deal intimately with port health had this in view throughout its discussions. The time may not be ripe yet for the constitution of a central health organisation on British lines; but no one who reads the signs of the times correctly can fail to see that such an organisation must in time be faced."

Major A. D. Stewart writes as follows:—"There has perhaps been little of note in domestic and public health legislation, either central or local. The Factories' Act is now in force throughout India, though some years must elapse before the benefit to the health of the rising generation is evidenced. The Workmen's Compensation Act is now general law and though cases of accident chiefly will be referred to it, the question of the deleterious effect of particular occupations on the workmen's health may possibly arise in the future. Political and financial reasons have probably been the cause of the dearth of public health legislation. Under the Calcutta Municipal Act of 1923, the Calcutta Corporation is now a thoroughly democratic body. The boundaries of the city have been largely extended and it yet remains to be seen how the Corporation proposes to tackle the many and difficult sanitary problems confronting it. The revision of the Bengal Municipal Act is long overdue and doubtless would have been undertaken but for the reasons above indicated. From a review of the annual reports of the Public Health Commissioner, India, and of the Directors of Public Health of the various provinces, it would appear that Bengal has given the lead in the matter of utilising local self-governing bodies in the prevention of disease. Each of the 26 districts of Bengal has now a District Health Officer who serves the District Board. The Government of Bengal in their review of the kala-azar problem recognises the stimulus that has been given to local sanitary endeavour during the last few years. A start has been made, though there are many difficulties that face the Health Officer, financial, legal, prejudice, antipathy and inertia.

Most provinces now have Food Adulteration Acts, though in some the absence of standards and laboratories has hindered action. Difficult as may be her own domestic sanitary problems, India cannot neglect the great importance and sanitary significance of her maritime trade; nor indeed are other countries, which fear importation of oriental disease, likely to let India forget her responsibility with regard to such infections as anthrax, plague, cholera and small-pox which may leave her shores. The position is somewhat complicated owing to the various and conflicting interests, commercial, social and financial, involved in the problem. The signatories to the International Sanitary Convention of 1912 were mainly concerned in preventing the entrance of oriental infectious diseases into their ports and territories, and the rules of this convention mainly refer to ships arriving at ports. All are agreed that revision of the convention is necessary and a draft revision has been prepared for ratification by the signatories. The League of Nations, however, since the treaty of Versailles, has interested itself in international sanitary problems and on its behalf Dr. Norman White made a special tour of the Far East to see how far the unratified revised convention was suitable to Far Eastern conditions; and whether a separate convention suitable

to Far Eastern conditions was desirable. Dr. Norman White in his report criticises the revised draft convention as unsuitable in its fundamentals and suggests a draft convention for quarantine procedure in Far Eastern areas where ports of departure and not ships are classified; and also the formation of a central International Epidemiological Intelligence Bureau for the Far East at Singapore. India's position is rather peculiar as it is represented directly on the International Board of Health which deals with the International Sanitary Convention, whilst it has no direct representation on the Health Committee of the League of Nations. The future developments will be awaited with interest—it is understood that the question of port sanitary authorities has received the close attention of the Government of India lately."

That serious steps are being taken to remedy the chief defects of public health administration in India will be evident to our readers. Thus in our issue for January 1924 an account was given of the ingenious methods adopted in Burma to try to ensure accuracy in the registration of vital statistics among an illiterate people; in our issue for last May we dealt with the reorganisation of the public health personnel in Madras, and in June and in the editorial for December with the scheme for the provision of a whole-time public health personnel in the United Provinces. To anyone interested in the immense questions of public health in India we would recommend a careful study of Lieutenant-Colonel S. R. Christophers' striking presidential address at the Medical Research Section of the Indian Science Congress, 1923, on "What Disease Costs India," published in our issue for last April, and one of the most thoughtful contributions to the question of public health work in India. The review of the medical aspects of the Indian census of 1921, published in our issue for last September, may also be not without interest. Such papers are in themselves so much of the nature of reviews that they cannot be reviewed.

Water Supplies.

Here there is a large volume of patient and careful work to review. Major Stewart writes that there has been a considerable expansion in the use of deep tube wells as a source of drinking water, especially in Bengal. Calcutta city is extending its present slow filtration system, whilst Bombay has practically decided to pass its large lake supplies through rapid sand filters, ensuring safety by chlorination. A considerable volume of work on water supplies has been published by the officers of the Bengal Public Health Laboratories. N. L. Bannerji deals with the pH reaction and the action of alum in clarification of water supplies. The optimum dose of alum requisite was found to vary with the pH present, and the total hardness of the water is important in this rôle. The dose of alum needed can be reduced by the preliminary addition of any cheap acid, such as sulphuric acid, and acid alum is preferable to basic alum. Here there is a lesson of great economic importance, since a great saving in the amounts of alum required may be effected.

Rao Sahib V. G. Raju describes the algal growths in the tank waters of Bengal. These, by their decay under the hot sun of the tropics, render the waters unfit for drinking. The chief causes of the decomposition are the accumulation of algal spores at the bottom and sides of the tanks, bicarbonates in the tank waters, the quiescence and transparency of the water, and an atmospheric temperature of about 75°C. He recommends thorough removal of the soil from the bottom and sides of tanks; the destruction of the bicarbonate by the addition of sulphuric acid; and to stop the practice of storing water in overhead reservoirs during the hottest part of the day when the heat kills the algae present. Major Stewart and the same author have studied the faecal organisms of surface waters in Bengal. *B. coli communis* was found to constitute 29 per cent. of the bacteria in human

faeces, 26 per cent. of those in septic tank effluents, but only 12 per cent. of those in cow-dung. In waters naturally purified it is rare; 70 per cent. of stored waters failed to shew it, whilst only 30 per cent. of waters stored for less than 18 hours shewed it, and here it constituted only 8 per cent. of the bacteria present. On the other hand the *B. neapolitans* is not so susceptible; it constitutes 32 per cent. of the bacteria in human faeces, 28 per cent. of those in latrine effluents, 37 per cent. of those in stored waters, and 51 per cent. of those in cow-dung. Advantage can be taken of the change in the bacterial flora in waters undergoing natural purification to differentiate a recently polluted water supply from one which has undergone natural purification. In water supplies recently polluted the *B. coli* content is at a high level, whereas it is nil in waters which have undergone prolonged storage.

With regard to the detailed chemical examination of filtered water, Rao Sahib V. G. Raju concludes that it does not give any reliable information about the bacterial efficiency of the filter. A study of the results obtained suggests that the nature of the organic matter and the condition in which it is present in the water are the chief factors which determine the amount that will be arrested during filtration, the condition of the filter bed and its filtering efficiency playing only a negligible part.

From Madras, Dr. Turkhud reports as follows:—

"The problem of finding out the best means of purifying the Madras city water supply engaged the attention of the committee on water filtration for nearly 2 years. In April 1923 the committee submitted a report to Government, pointing out that they had always been aware that mechanical filtration has been the correct method of purifying the supply, but that with the slow sand filtration plant already in existence their experiments up to that time had been directed towards discovering a method of making the existing plant work satisfactorily. All attempts had so far proved unsatisfactory, but the possibilities had been narrowed down considerably, and should the experiments then in progress fail to give satisfactory results, then no alternative would remain to the introduction of mechanical filtration. These final experiments were completed during the course of the summer. This want of success convinced Mr. Madeley, the Special Engineer to the Corporation of Madras, that the committee's original opinion that mechanical filtration was the only method which would give satisfactory results was correct, and he placed a detailed scheme for the modification of the present plant on a mechanical filtration basis before the Madras Corporation in his note of the 8th November, 1923. A second report dealing with Mr. Madeley's note and giving a complete summary of the whole situation with the committee's recommendation was forwarded to Government with the president of the committee's letter dated 13th June, 1924. The arguments for mechanical filtration advanced in this report are unanswerable. The problem of the Madras City water supply, so far as the committee is concerned, may therefore be considered as solved. It now remains to be seen whether the Madras Corporation will act upon the advice given by the committee.

(2) Experiments at the experimental filter installation in the compound of the King Institute of Preventive Medicine at Guindy are being continued. The experiments now in progress relate to the testing of the effect of a preliminary filtering of slow sand filters with alum. Results available so far show that the method is a promising one for certain types of water.

(3) The bacteriology of water supplies has been the subject of detailed study at the King Institute, Guindy, by Lieutenant-Colonel J. Cunningham and Mr. T. N. S. Raghavachari. They have followed up the work of the American water bacteriologists, based on the hydrogen-ion concentration produced by lactose fermentors in suitably buffered culture media, with a view to testing

the applicability or otherwise of these tests to Indian conditions, and also with the object of finding out if the application of these or other tests will yield a classification affording evidence of the origin of coliform bacteria found in water. In the preliminary paper which they have published are given the results of the examination of lactose fermentors derived from human and bovine faeces, and from samples of unfiltered water from rivers, impounded reservoirs and wells. They have reached the conclusion that their results agree with those obtained by other observers in different parts of the world and that they have not, up to the point they have reached, found any clue to the probable source of the organisms found in water. In their examination of human faeces they have had a unique opportunity—not to be obtained in any other country—of examining a totally vegetarian as well as a non-vegetarian community. The percentage of the high ratio group of organisms in vegetarians was 4.6 per cent. as against 0.4 per cent. for the non-vegetarians. This was an unexpected result, seeing that one would expect the vegetarian human faeces to approach more nearly to the bovine type, on account of the similarity of their diets.

Further work relating to lactose fermentors found in soil, grain and milk has been in progress during the year.

(4) The same authors have carried out an exhaustive study of a violet-producing organism which repeatedly appeared in 3 different water supplies, situated too far away from one another to have been derived from a common source. Except for certain minor deviations, this organism resembled the *B. violaceum* described by Lehmann and Neumann.

(5) Water supplies, using both bleaching powder and liquid chlorine for sterilisation, were systematically tested for efficiency, and expert advice offered whenever defects were noticed. One of the Paterson's chloronome plants installed at Fort St. George was thus tested and found to be too large for the supply and reported as such.

(6) A systematic investigation into the most suitable method of treating the water of the Narsapur canal with a view to using it as the water supply for Palacole Municipality was undertaken and brought to a successful issue. Mechanical filtration followed by systematic chlorination, has been recommended.

(7) The Fisheries Department of Government was faced with a peculiar growth that had been occurring in certain samples of dried fish, and wished to have the matter investigated from the point of view of their fitness for human consumption. The investigation showed that this discolouration was due to the growth of an organism called 'Rhodococcus,' and was the same as a condition which had just then been reported as occurring in England due to the same cause. It was advised that the dried fish which grew these organisms should be rejected as unfit for human consumption."

Vaccination.

In an interesting paper, Lieutenant-Colonel J. Cunningham and Major J. A. Cruickshank compare the relative values of lanoline and glycerine as vehicles for vaccine lymph in the tropics. They conclude (a) that untreated glycerine lymph is better than lanoline lymph under tropical conditions; (b) the former gives an average case success rate of 89 to 91 per cent., as against corresponding figures of 49 to 70 per cent. with lanoline lymph, whilst the vesicles produced are better and more typical with glycerinated lymph. Also the glycerinated lymph tends to keep better over a ten-day period.

In connection with further researches carried out during the year at the King Institute, Dr. Turkhud reports as follows:—

"(a) Routine Manufacture.—With Nijland's technique the potency of seed lymph is well maintained.

The 'vesiculation test' introduced by Cunningham and Cruickshank continues to serve as a reliable guide in judging the potency of routine lymph.

(b) *Research Work.*—(1) Experiments in lymph purification:—

The following methods of purifying the vaccine lymph have been tested under the conditions which obtain in the Madras Presidency. The experiments were carried out by Lieutenant-Colonel J. Cunningham, Major J. A. Cruickshank and Drs. D. A. Turkhud and C. G. Pandit:—

- (a) Chloroforming.
- (b) Ether.
- (c) Clove oil.
- (d) Brilliant green.
- (e) Untreated glycerine.

The results obtained are as follows:—

(a) Chloroforming lymph reduced the bacterial content to its correct limits; exposure for 10 to 12 minutes produces least deterioration in the potency.

(b) Sterilisation by ether was found to take too long, and to be uncertain in its effects.

(c) Clove oil proved to be a satisfactory reagent for purification purposes; the time required was 4 days' exposure, and the amount of deterioration of potency was small.

(d) Brilliant green in dilutions of 1 in 10,000 and 1 in 5,000 produced satisfactory bacterial purification in about 4 days; the loss of potency was inappreciable. The great disadvantage of this method is the extreme care that is required in the addition of sodium hydro-sulphite to stop the further action of brilliant green.

(e) Glycerine lymph without any particular treatment is purified to a satisfactory degree within 4 days of exposure to the ordinary temperatures found in the Madras Presidency. As the amount of deterioration in the lymph produced by the glycerine is a common factor to all methods of purification, and as the more rapid methods of purification may produce further deterioration, there is no advantage in introducing any of these rapid methods.

The authors therefore recommend that no special means of purification be introduced, and that untreated glycerine lymph be the authorised lymph for issue to the Madras Presidency.

(2) Other experiments were also done to obtain lymph free from contaminating bacteria. They tried the use of phenol (1 per cent.) and the action of light of different wave lengths. The latter was tested by the use of Wratten filters (Kodak). The effect of arc light, red and green light was then investigated, the time of exposure of lymph to light having been calculated in each case. Bacterial contamination was thus reduced to a third, while there was no reduction in the potency of the virus.

(3) *Studies in vaccinal and variolar immunity.*—Cunningham, Turkhud and Pandit have attempted to obtain evidence regarding the principle tissue concerned in the production of immunity. They have examined various tissues obtained from rabbits immunised by skin vaccination with a potent virus. So far they conclude that the specific immune substance resides chiefly in the serum and a little in the skin. Spleen, liver, brain ovaries and testes were all examined, but failed to show any evidence in this respect.

The reaction obtained with serum was very definite. Sera obtained from persons who had had an attack of small-pox some time or other showed a marked vaccinal effect, in one case though the attack was some twenty years ago. The same effect was also obtained with sera of persons who were only successfully vaccinated against it. It is now being investigated if this property of serum can be utilized in determining the degree of immunity in an individual.

Immunity studies in rabbits have also furnished some interesting results. Immunity in them is of a very short duration—the average in rabbits so far examined

being only 1½ to 2 months. In this respect different tissues seem to react differently. It appears that the cornea loses the immunity first, the skin follows next. The blood, however, retains it for a considerably longer period."

General.

Major Stewart reports that anti-cholera inoculation on a large scale has now been started in Bengal and has given very encouraging results. With regard to the treatment of sewage, the Chief Engineer, Bengal Public Health Department, has demonstrated successfully the possibility of the treatment of town sewage by land treatment in the unlikely soil of the Ganges' delta; large crops of sugar-cane and other grasses have been obtained, and this method of disposal is likely to become more and more widely practised in India as being both efficacious and economical. Dr. J. W. Tomb describes in our issue for last February a specially designed jar for the storage and preservation of chloride of lime.

Rabies.

Dr. E. C. R. Fox, I.M.D., Superintendent of the newly opened Pasteur Institute at Calcutta, writes as follows:—

"During the year a Pasteur Institute was opened in Calcutta. It rapidly became popular, owing to the convenience with which patients can get to Calcutta from all parts of Bengal. It has already treated about 1,400 patients in its first six months' work.

The issue of antirabic vaccine from Coonoor and Parel has been extended during the year to Indian States, military hospitals and railway headquarters. The first year's statistics of those treated in the Madras Presidency show that as good results are obtained by this system, as when treatment was available at Coonoor only. The reports for 1923 from all the Pasteur Institutes in India and Burma shew a steady increase in the number of patients coming for treatment. In this connection it may be of interest to compare the year 1914 with 1924. In the former year there were only two institutes open, Kasauli and Coonoor, which treated altogether 5,795 patients. In 1924 there were six institutes, and they treated more than 18,000 patients.

Major J. Morrison introduced the intravenous injection of antirabic vaccine at Parel in 1923 and continued it in 1924. The results so far are not conclusive, but the fact has been demonstrated that, given carefully, the treatment is safe.

Fresh interest in the organisms associated with rabies has been raised by the work of Levatidi and his collaborators on the virus of epidemic encephalitis and on other filter-passers, and it has already led Manouélian and Viala to describe their findings in rabies under the name *Encephalitozoon rabiei*. This work, however, requires confirmation.

Interesting figures are given in the report of the Pasteur Institute, Coonoor, shewing that the risk of dying from hydrophobia in persons bitten by rabid animals which are certainly infective is not less than 1 in 3, and that this risk may be diminished by one-half by antirabic treatment."

(In connection with Dr. Fox's notes, the writer begs to acknowledge the kindness of Lieutenant-Colonel J. W. Cornwall in supplying notes and information.)

MIDWIFERY AND GYNÆCOLOGY.

Miss M. I. Balfour reviews Dr. Janet Campbell's special report to the Ministry of Health, Great Britain, on the maternal mortality during childbirth, with special reference to Indian conditions. Conditions in England shew but little improvement during recent years, and, if so, what can be expected in India? There are several possible methods of advance, however; first, improvement in the quality of the professional attendance provided; secondly, ante-natal supervision, the supply and

control of midwives, the supply of sterile maternity outfits, and the appointment of obstetric consultants under action through the local public health authorities; and thirdly, social and educational measures. Indian maternal mortality rates average about 14 per mille, and must total about 109,000 or more deaths per annum. Ante-natal supervision can be introduced if every practitioner will create his own centre for such supervision; obstetric consultants suitable for India can be supplied in the form of trained lady doctors; whilst the training of midwives and *dois* is being steadily improved. By degrees very considerable and necessary advances are possible, if only the requisite efforts be made. Major V. B. Green Armytage stresses the same necessity for a scheme of ante-natal welfare in India, insisting on the need for the creation of ante-natal clinics, and giving a diagrammatic scheme for the examination of the expectant mother. Propaganda, efficient training of midwives, and co-operation on the part of the medical profession, he claims, are what are wanted. In a further and interesting clinical lecture to post-graduate students, he deals with infant feeding and the alimentary disorders of infancy.

National Health and Baby Week was celebrated all over India in January 1924, and in the main the results were both encouraging and successful. Sets of lantern slides and specimen lectures and demonstrations and illustrated leaflets were prepared and much propaganda work carried out in the vernaculars. Wall posters were a prominent feature of the effort in many presidency and provincial centres.

Major V. B. Green Armytage deals with the difficult problem of the efficient teaching of midwifery to Indian students in centres where facilities are scarce. He advocates the use of a felt or wool-lined wooden dummy model of the female pelvis and of a live baby, the demonstrations being given to classes of not more than 20 students in a warm room adjacent to a lying-in ward.

With regard to difficult labour, Major A. G. Tressider records the following cases as typical of Indian conditions:—(a) a 7-para with all previous children still-born, premature rupture of the membranes and a sluggish uterus. Successful labour with the birth of a living child was secured by the use of a *de Ribes* bag; (b) sluggish uterus and oblique presentation in a patient 44 years of age; Caesarean section was resorted to, but the child died from asphyxia six hours after birth; (c) a previous ventro-fixation necessitating Caesarean section; and (d) placenta praevia necessitating Caesarean section. Here he points out that the indications for Caesarean section in such cases are (1) when the haemorrhage has not been excessive and the maternal pulse is full and not more than 100 per minute, (2) when the cervix is undilated, rigid, and dilatation likely to be unduly prolonged, as in elderly primiparae, (3) where there is no previous likelihood of septic contamination, (4) with the pregnancy at full term and the foetal heart sounds active, (5) with disproportionate measurements between the size of foetal head and maternal pelvis, and (6) where the parents are particularly desirous of a living child; (e) eclampsia necessitating Caesarean section, where the foetus was dead, and the mother's life in imminent danger; and (f) dystocia with small round pelvis, necessitating Caesarean section, both mother and child surviving. His articles shew something of the unexpected difficulties which may be encountered in routine Indian midwifery practice.

R. Garg records a case of internal version in flattened pelvis, this method of delivery being in his opinion better than the attempt to apply "high" forceps, which often means forceps above the brim; and Captain N. N. Ghosh (T.C.) a case where intra-cardiac injection of $\frac{1}{2}$ c.c. of liquor adrenalin, 1 in 1,000, restored respiration in a case of a child born in a condition of white asphyxia. S. N. Misra records a case of missed labour of 15½ months' gestation, with delivery of a macerated foetus and recovery on the part of the mother; and

V. A. Krishnamurty a case of the tetany of pregnancy with onset at the 7th month of pregnancy, of 5 weeks' duration, and relieved by adrenalin injections. N. N. Ghosh discusses the question of the treatment of puerperal tetanus. It differs from tetanus due to superficial wounds in that the site of infection cannot be sterilised. He advocates repeated intravenous and intramuscular injections of anti-tetanic serum in doses of 1,500 to 3,000 units, especially by the intravenous route, and records successful results.

In gynaecology Dr. G. B. Archer records the case of a patient suffering from an enormous monolocular ovarian cyst, successfully removed. Before operation the patient plus cyst weighed 168 lbs., whereas after operation the patient without the cyst weighed only 67½ lbs., so that the cyst weighed considerably more than the patient. Dr. A. H. Driver calls attention to a "treatment" for prolapsus uteri which consists of the introduction into the vagina of the fruit of the wood apple, *Aegle marmelos*, which is often *in situ* for years. This is somewhat larger than and as hard as a cricket ball, and removal can often only be accomplished by the use of midwifery forceps. Lieutenant-Colonel J. C. Holdich Leicester draws attention to the publication during the year of V. de Werselow's "Toxæmias of Pregnancy" by J. M. Wyatt, Constable & Co.; and to the discussion in American and other journals of the pros and cons of radium versus operation in carcinoma of the cervix uteri.

OPHTHALMOLOGY.

Major R. E. Wright reviews the year as follows:—

"B. B. Mallick and P. C. Gupta record an orbital fibroma surrounding the globe and causing proptosis, of 3 years' duration in a Hindu, male, aged 35, removed successfully by Major Coutts with subsequent full vision.

Major Dickson, R.A.M.C., discusses butyn versus cocaine. He states 'in ophthalmic surgery at least butyn appears to be more than a substitute as it is superior to cocaine in several respects.' He enumerates all its advantages for instillation work. He recommends its use also for infiltration operations. He quotes Mathra Dass as holding that prolapse of iris following expression is a criterion of efficiency of local anaesthesia. He states that prolapse is more common after expression under deteriorated cocaine and less frequent after butyn, but states that the subject requires further investigation. Major Dickson emphasises that cocaine addiction is more common in India than is generally recognised. This important subject has been very fully dealt with both in England and America during the year and the pros and cons dealt with at length in the literature. Many of the advantages set forth above have been contested by research workers. It is noteworthy that butyn has not replaced cocaine in many large eye clinics. Cocaine should always be used fresh, otherwise is more dangerous. The popularity of cocaine among the Indian public appears to be due to its aphrodisiac action. Butyn has certain advantages, but few workers consider it so suitable as novocaine for infiltration operations in ophthalmic practice.

A. D. Shroff reports a case in which a scale of iron lying on the retina did not respond to the giant magnet till an attempt on the third day in succession, when it moved slightly, but not till a small incision was made in the sclera could it be extracted. The pull of the magnet did not cause any painful sensation.

Dr. W. A. Fischer describes a day at the Shikarpur clinic. The cataract work is done there in the 'season,' January 1 to February 15. In over 95 per cent. expression is performed. One hundred cataracts were done in the day under review. Rai Bahadur Kishendas Premchand finances the work which is in charge of Dr. T.

H. Holland of the Church of England Mission and the charity does splendid work. The various missions furnish a vast amount of ophthalmic relief in India, for example that at Tirupatur with Kugelberg in charge, and the Eye Clinic of Dr. Ida Scudder's Medical School at Vellore. Shikarpur is probably unique in being financed by an Indian philanthropist.

B. K. Narayana Row describes a case of a nervous female who developed exophthalmos during preparation for cataract operation in the cocaineid eye. The patient had a rapid pulse and cystic goitre, but lacked most of the common symptoms of Grave's disease. The same author mentions a case of syphilitic hemianæsthesia with corneal ulcer cured by antisyphilitic treatment, and two cases of unilateral crystalline sychisis scintillans in patients of 28 and 40 respectively.

Major R. E. Wright records a rare case of encysted guinea-worm of the orbit. The specimen was identified by Prof. Leiper. The same author pleads for greater facilities for obtaining glass eyes in India and for special centres for the treatment of trachoma. He emphasises the importance of a knowledge of muscle-balance work in prescribing spectacles. He refers to the value of Lumière colour photography as a teaching method. He advocates dacryocystorhinostomy instead of West's operation in similar cases. He refers to the value of slit lamp microscopy, attention to which has been drawn elsewhere in our columns, and to the progress that has been made by its use in the hands of Vögt and Koeppe. Instruction in its use is available in the Madras clinic. Ophthalmoscopy by red-free light as a valuable addition to the methods for the study of fundus disease is noted. The experimental production of cataract in rabbits by infra-red rays he considers may throw light on the ætiology of cataract in India. The importance of protection against the infra-red is emphasised. Delhi green glass is mentioned as a possibility. Of late the limitations of Crookes' glasses for the tropics have been noted and peacock blue suggested. This subject is important. The way in which different tinted glasses are 'boosted' by opticians and empirically prescribed by medical men leaves much to be desired. Major Wright refers to von Szily's experimental production of cataract in young rats by depriving the mother of fat soluble vitamin A, and the possibilities foreshadowed correlating inadequate diet and cataract in India. In Madras, cataract is not associated with keratomalacia in the child. The child of a keratomalacic mother may be predisposed to cataract, but the association has not been observed.

The modern electric ophthalmoscope is discussed in an article by the same author and improvements suggested. These have been incorporated in the New Madras Model by Hamblin. A successful case of Dffenbach's procedure for reconstruction of the lower lid with a cheek flap and combined skin cartilage graft from the ear is published. In analysing 250 cases of Barraquer's operation, he discusses the possible effects on the solid elements of the vitreous which take origin from the ciliary region. He does not consider the procedure suitable for the type of cataract cases dealt with in Madras. He publishes a description of an operation for large corneal staphyloma by trephining and radial cauterisation of the ectatic scar tissue, giving reasons for its adoption, based on the fact that in a large number of eyes enucleated for staphyloma examined by him the posterior segment is normal, and if in such the tension could be kept down, there is no reason why the posterior segment should not remain so with the retention of light perception. The cauterisation reduces the ectasia without opening the globe. Major Wright and Lieutenant-Colonel Cunningham have conducted investigations on the strains of pneumococci responsible for hypopion ulcer, with a view to grouping and subsequent anti-serum therapy. The same investigators have carried out experimental work on the transmission of the trachoma virus, using the subdural and intracerebral

routes in rabbits. Lieutenant-Colonel J. W. Cornwall has repeated some of the work.

Nimbkar points out the prevalence of bifocals amongst young persons wearing spectacles and the necessity for ordering bifocals only in those cases where they are absolutely indicated. There appears to be a vogue for lay persons asking for and ignorant doctors ordering unnecessary bifocals in the south of India, and they are frequently of bad pattern.

In his 1923 report Major Wright records 1,613 cataract operations; success rate 88 per cent., vitreous loss rate 1.23 per cent. With few exceptions the capsulotomy method is adopted. Primary capsule rupture, introduced by Drake Brochman in 1879, is still in vogue. Captain Verdon, who performed the bulk of the operations for the year, carried out one series of 376 in which he adopted a small peripheral iridectomy after delivery with very good results, 1.8 per cent. iris prolapse. Elliot's sclero-corneal trephining is still the operation of choice. In 7 cases said to be blind for more than 3 months some vision was regained in 2 after trephining. The report records 70 cases of keratomalacia. Of these 22 were unsuccessfully treated with sardine oil on the suggestion of McCarrison (instead of with cod-liver oil); it gave rise to diarrhoea. Thirty-six cases of Herbert's wedge isolation in glaucoma are analysed by Koman Nayar. Interesting case reports of long-standing iridocyclitis due to nasal sinus disease, pyocyanus ulcer of the cornea, Mikulicz's disease recovering under x-rays, Parinaud's conjunctivitis, cavernous sinus thrombosis, and syphilitic meningo-encephalitis are detailed. The various members of the staff contribute to the report.

Major Wright summarises two publications issued by the Madras Government Press dealing with fundus diseases, prepared by him and his staff from the notes on patients subjected to special case taking in the Madras clinic from 1919-1922. One deals with 418 cases of diseases of the optic nerve. Syphilis accounts for 50 per cent.; of these 7 per cent. are simple atrophies including 5 cases of tabes (classical tabes is rare). Nerve diseases of unknown origin number 21 per cent. Amongst the remaining 29 per cent. were 16 cases due to arterio-sclerosis, 8 cases of atrophy due to pituitary enlargement or neighbourhood tumours, 5 of brain tumours, 11 of diabetes, 9 of albuminuria, 6 of meningitis, 'following child birth' 6 cases, malnutrition 9 cases, and one case each due to quinine, methyl alcohol, sphenoidal sinus disease, leprosy, malaria, occlusion of the central artery. Tobacco and alcohol were not incriminated. The other pamphlet 'Diseases of the Choroid, Retina, etc.' deals with 434 cases. The optic nerve was also affected in a number, so that certain cases recorded here are omitted from the preceding publication and vice versa. Again syphilis was responsible for over 50 per cent., retinitis pigmentosa was met with 64 times. Sugar was the chief factor in 17 cases, although 6 of these had syphilis. In only two was typical diabetic retinitis seen. Albuminuria was noted 43 times. In 26 of these (uncomplicated by syphilis or sugar, etc.) 13 showed characteristic albuminuric retinitis and 13 were atypical. The figures for arterio-sclerotic changes will be dealt with later."

K. N. Pradhan extols the value of electrolysis in trichiasis and records a case of traumatic rupture of the retina. The same author also describes a case of slight rupture of the retina by a tennis ball, with recovery under eserine instillations.

Dr. John Weeks, of New York, one of the most senior and distinguished ophthalmologists in America, visited some of the eye clinics in connection with the Indian universities early in the year and expressed himself highly pleased at the large amount of valuable work done in these institutions and their high state of efficiency.

Dr. H. T. Holland describes hereditary glaucoma affecting three generations; a mother blind at 50; four

of her sons blind respectively at 60, 60, 55 and 50 years of age, and a son of the third son almost blind at 30. A broad iridectomy was done on the last case in the eye which could still distinguish hand movements, with some improvement of vision.

One of the most important events of the year has been the formation of a strong committee in England under Sir Arthur Lawley and Lord Carmichael to organise and support measures against blindness in India and to help the work of the Blind Relief Association. The committee point out that there are 1 to 1½ million totally blind in every generation born in India to-day.

Dr. E. F. Neve contributes the following notes in connection with cataract extraction:—

"Barraquer's operation is still on its trial. In 1923 Major R. E. Wright reported 250 cases with 80 per cent. of complete successes as against 88 per cent. by the ordinary capsulotomy operation. Barraquer read a paper at the 1924 meeting of the British Medical Association, but in the discussion which followed the paper the balance of opinion was against it. It is doubtful whether Sinclair's method of extraction with specially designed forceps will meet with a more favourable reception in Europe. The great advantage of intraocular irrigation is the rarity of vitreous loss. Lieutenant-Colonel E. A. R. Newman, in a recent brochure, 'Irrigation in Cataract Extraction,' gives a record of 1,000 cases. Vitreous was lost on 36 occasions, a percentage of 3.8, and a lower proportion than the last Shikarpur record for intracapsular extraction which was 10.6 per cent. Only 9 of Colonel Newman's cases of vitreous loss resulted from the use of the irrigator; the others followed the use of forceps for extracting the capsule or followed the section before irrigation was commenced. These last were doubtless due to high tension. The use of the tonometer, if systematic, gives useful fore-warning.

Too much emphasis cannot be laid on the observance of antiseptic precautions. In cases where there is the least doubt, the conjunctival secretion should be examined bacteriologically and preliminary treatment carried out."

MEDICAL ENTOMOLOGY.

Dr. C. Strickland kindly contributes the following review of the year:—

"Medical entomology is conveniently considered in two water-tight compartments; one containing the creatures which come within the purview of the clinician, the other of the sanitarian.

(1) Among the 'clinical' sections we have a paper by D. Walsh who recommends for general use in insect-bites and stings the use of an ointment of dimol.

The other papers referred to are classified as follows:—

Muscoids. Warbles caused by the Oestrid fly, *Hypoderma lineatum*, have been found under the skin of a child by Cooley, also by Style: in the latter case the author suggests that the eggs had been laid in the ordinary way on a cow's hair, the milk of the cow had been accidentally contaminated by the eggs, and the child had drunk the milk and infected himself. Major Patton has reported that this fly is a common parasite of cows and goats in India. **Myiasis.** Keilin records infestation of the human intestine by flesh-fly maggots (*Sarcophagids*) which appear to live and develop normally in such a habitat: Major C. E. Southon's report is quoted:—"A sepoy aged 30, a suspected ankylostomiasis case, was given a eucalyptus mixture and passed 40 to 50 of the maggots." Leger and Couput have reported infection

of the nasal cavity of a patient with 70 maggots of the fly *Chrysomya duar*.

Beetles. M. O. T. Iyengar has noted the infestation of a child by a coprophagous beetle, *Caccobius milans*. Mr. Bainbrigge Fletcher discusses the occurrence of Scarabacids in Indian children and thinks that adult beetles enter the anus of sleeping children in search of food. Strickland has identified the cause of the common Indian affection 'spider-lick' to be one of the blister-beetles, *Poederus fuscipes*."

"**Mange, Mites, and Mite-Affections.**—H. E. Cross draws attention to the frequent transmission of mange from camels to man, with great accompanying irritation and sometimes suppurating sores. Kishida reports a mite in human urine (Mackenzie, however, has considered such cases to be due to accidental contamination). **Ticks.**—Blanc and Camenopetras note the removability of ticks causing 'tick paralysis' by covering them with an oil.

Scorpions.—Dr. Tomb has treated scorpion sting with *Liq. ammon. fort.* (B.P.) and has found that it gives immediate relief from pain.

Tongue-worms.—Fornara reports the occurrence of Linguatulids in a hernial sac and on the occipital lobe of the brain. In the latter case death followed with symptoms of acute meningitis.

Leeches.—Messinger describes the case of a woman who swallowed a live leech which accommodated itself below the vocal cords and caused much trouble before it was evacuated.

(2) In the public health compartment must be included papers on systematic entomological work, between which and those of more direct importance to hygiene no hard and fast line can be drawn; however, papers reviewed above under special diseases are not further noticed.

Mosquitos.—Captain Barraud has continued his valuable work on the 'Revision of the Culicine Mosquitos of India' in a series of papers and employs a wonderful series of plates illustrating them. Lieutenant-Colonel S. R. Christophers and Captain Barraud discuss the tracheation and wing venation of the mosquito, whilst Colonel Christophers in two papers has defined further the grouping of some of the Indian anophelines. Iyengar has described a new species of anopheline common in Bengal which he names *varuna*; it is annectant to *listoni* and *minimus*. Strickland on the other hand considers that there are no definable points of distinction between the African *funestus*, its Indian variety *listoni*, and *minimus*, and that therefore all these forms should be considered merely geographical races of *funestus*; *aconitus* on the other hand he considers a distinct form entitled to specific rank.

Fleas and plague.—Major Taylor and Dr. Chitré have succeeded in transmitting plague to rats and guinea-pigs through the agency of *X. astia* and conclude that the negative results of similar experiments by Hirst in Colombo were due to its climatic conditions being unsuitable.

Cockroaches.—Toda thinks that these insects may occasionally be the instrument of transmission of cholera.

Ticks.—Colonel Megaw has brought forward evidence that the carrier of certain typhus-like exanthemata in India may be *Rhipicephalus sanguineus*, which is not a very distant relation to *Dermacentor venustus*, the carrier of Rocky Mountain typhus.

Lice and Relapsing Fever.—Major A. J. H. Russell, and Drs. A. Ayyar and Ubhaya have studied outbreaks of this disease in the Madras Presidency during the cooler months and conclude that they were louse-borne.

Sandflies.—Major J. A. Sinton continues his monograph on the Indian and Ceylon *Phlebotomus*. Their connection with the transmission of specific fevers is dealt with elsewhere.

Dracontiasis.—Dr. Hamilton Fairley and Lieutenant-Colonel W. Glen Liston have contributed a number of articles dealing with the parasite in Cyclops.

Bowel diseases.—Janson and Dekester conclude that the part played by 'flies' in the spread of amœbiasis must be small.

Technique.—Major H. E. Shortt contributes an account of a method which he has devised for taking stereoscopic photographs of insects or other small objects."

LABORATORY METHODS AND VACCINE THERAPY.

Several interesting advances in laboratory technique, etc., have been published in India during the year. Captain R. H. Malone introduces a new and simple method of preparing collodion capsules for use in the study of biological problems; and Dr. S. N. Goré a simple method of preparing tenth dilutions. Dr. Goré has also worked out a simple method of detecting and estimating indican in the urine by an adaptation of his cotton-wool plug test, to replace Obermeyer's test. It is claimed that the new method is more simple, rapid and economical than Obermeyer's; also it is not affected by the drugs taken by the patient. A quantitative method is outlined by which by dilution of the urine the amount of indican present can be expressed in terms of indol equivalent.

Captain G. Shanks emphasises the very great value—necessity almost—for taking routine blood cultures in all cases of pyrexia of uncertain origin. He instances unsuspected infections with *B. pestis*, and streptococcal, staphylococcal, *B. influenza* and pneumococcus bacteræmias diagnosed by this method. Routine blood culture will often confirm a tentative diagnosis; not infrequently the diagnosis can be made by no other method; sometimes it furnishes an unexpected surprise. D. N. Bannerjee has studied the normal Arneeth index in 100 healthy Bengalis and finds that it presents an unexpected shift to the left, 52.55; and discusses whether this may be due to residence in a tropical climate or to latent malaria.

In the standardisation of vaccines, Lieutenant-Colonel J. Cunningham and Sub-Assistant Surgeon B. Timothy give a comparison of hæmocytometer values with Brown's opacity tube values. Colonel Cunningham and Assistant Surgeon Ramakrishnan have also studied 141 unselected strains of streptococci isolated from the routine specimens sent to the King Institute for examination; e.g., infections of the throat, ear, lungs, teeth, joints, intestine, uterus, bladder, cerebro-spinal fluid, etc., with a view to differentiating them on the basis of Holman's classification. Hæmolytic and non-hæmolytic streptococci have been found in almost equal numbers, the former being slightly in excess. The frequency-distribution of the various sub-groups of each of these two divisions differed markedly from the results of other observers, which again differ amongst themselves to a certain extent. If, however, the strains derived from skin lesions were omitted, the results obtained at the King Institute did not differ very much from those of Holman, Blake, and Fisk and Burky, who were all working on organisms from definite pathological lesions of a severe type.

SKIN DISEASES.

The work of investigating and classifying the skin diseases of the tropics continues in Major Acton's clinic at the Calcutta School of Tropical Medicine, and promises soon to yield valuable results for publication. This work has been greatly assisted by the services of that veteran artist Mr. B. L. Das, who illustrated Sir

Leonard Rogers' books. In our January 1924 issue we gave a résumé of Major Acton's paper on some rare skin diseases of the tropics; he dealt with dermatolysis of the face, epidermolysis bullosa—an extraordinary condition in which the skin of the body blisters wherever the clothing presses upon it, and at all points of pressure—mycosis fungoides, and scleroderma,—for the treatment of which last condition he advocates the administration of thyroid extract.

The same author, with Miss D. F. Curjel, describes the curious occupation dermatitis of jute workers. Those working at retting jute have their arms constantly immersed in the baths, and a non-suppurative folliculitis follows, caused by the mechanical blocking of the sebaceous gland orifices by plugs of the unexfoliated stratum corneum. The remedy is soap and water freely used.

From the same clinic G. Panja contributes two papers; the first on common skin diseases of the tropics. Several factors are concerned in such conditions; thus as regards age, leprosy and elephantiasis are very rare in children; in sex, mangoe toe is especially seen in adult women who carry out domestic duties in the courtyards of their houses barefooted, whilst unmarried girls suffering from leucoderma come for treatment of the condition with a view to improving marriage prospects. As regards occupation he quotes the callosities seen in Ooriya dandy-bearers; as regards season, staphylococcal infections are especially seen in the hot weather, and ringworm infections in the monsoon. The general practitioner is all too apt to mistake such common diseases as psoriasis, folliculitis and true leucoderma for syphilis. In the vesicles of "eczema," streptococci and fine yeasts are very common, and the condition is really a streptococcal dermatitis.

The same author deals with seborrhœic dermatitis in a second paper; varieties noted being dandruff, pityriasis steatodes of the scalp, seborrhœa olea associated with acne, and seborrhœa corporis. The organism responsible for the disease is the bottle bacillus of Unna, and the diagnosis can be established by microscopical examination. In treatment of an infected scalp, the crusts should be removed with ether soap, and the scalp should be washed daily with a lotion of sulphur or resorcin and ether soap. Salicylic acid and ichthyol may also be useful. In cases where the body is affected we have papular, nummular, circinate, psoriaform and eczematous types of lesions. The face, neck, lips, trunk and extremities may be affected,—the forehead frequently, whilst the scalp is frequently infected first. A sulphur or salicylic acid ointment or lotion should be prescribed, followed by a bath next morning. A dusting powder which has been found very useful generally in the clinic, and especially so for prickly heat has the following composition:—precipitated sulphur, 1 oz.; camphor, 1 oz.; zinc oxide, 2 ozs.; with talcum powder 3 ozs.

In a note on the cause of pemphigus contagiosus (Manson), published by Lieutenant-Colonel J. Cunningham and Assistant Surgeon Ramakrishnan, these authors have determined the exact position of the streptococcus which they find to be invariably isolated from cases of this infection. The cultural and biochemical reactions of this coccus have been examined in great detail, and the organism, which answers in every detail to the *Streptococcus subacidus* of Holman, has been definitely proved to be the cause of this affection. A vaccine prepared with this organism has proved most successful in the treatment of the disease.

MEDICO-LEGAL, POISONS.

In our contemporary *The Madras Medical Journal*, September number, a medico-legal case of interest and importance is reported from Palghat by A. N. Verghese and Venkatachella Aiyar (journalist). The defence produced expert medical evidence to the effect that the prisoners charged with gouging out the eye with the

finger were innocent, as this was not feasible without rupture of the globe. Lyon's *Medical Jurisprudence* was quoted in support and was held to refer to gouging the contents of the eyeball and not to removing the unruptured eyeball from its socket. Major R. E. Wright, called as expert witness by the prosecution, produced much evidence from the literature to show that avulsion of the eyeball by the finger was quite feasible and that Chever, as recorded in Lyon's work, appeared to use the term gouging loosely to include rupture as well as avulsion, that in face of other authorities such as Parsons, Ball, Axenfeld, Lyon's *Jurisprudence* could not be considered authoritative. He held that the eyeball submitted to him was avulsed either by the finger or a blunt instrument. The nerve was long and the sheath torn near the optic foramen. The nerve end and muscle endings when subjected to microscopic examination appeared torn. Of over 700 eyeballs investigated by him in the Elliot School museum only one specimen showed a nerve as long as that under investigation. In this case the eyeball was gouged out by the horn of a bull. The practice of avulsion by insanes was mentioned and instances quoted from literature. The defence referred to the weakest point of the optic nerve as just behind the eye. The prosecution expert allowed that this was where the nerve would give way if broken inside the intact sheath, but that when the globe was dragged upon the sheath gives way far back.

The case is important as showing the undue importance which may be attached to an old and inexperienced record laid down in a work which the law accepts as authoritative, namely Chever's on gouging as recorded in Lyon's *Jurisprudence*.

The accused were convicted.

Major R. B. Lloyd and Captain S. N. Chandra (T.C.) give a technique for the preparation of permanent stained specimens of red corpuscles from old blood clots, using clear centrifuged serum to soak the clot, and subsequently Leishman's stain. Major Clive Newcomb has studied the keeping properties of old blood stains. Up to two months all tests for blood were positive; after a year the guaiacum-turpentine and micro-spectroscopic test with cyanide and ammonium sulphide were positive, but the reduced hæmatin spectrum test failed.

The same author contributes an interesting article on the injuries produced by firearms at short ranges, with a view to detecting the weapon used. With a black powder gun the grains of black powder are recognisable at ranges up to 10 feet; in the case of a shot-gun the wound produced is a large ragged hole; with a revolver, unburnt grains of cordite can be recognised at ranges below 5 feet, whereas with long barrelled guns firing smokeless powder, no unburnt cordite grains could be detected at any range, however close.

Rai Bahadur J. P. Modi and D. N. Chatterji have studied the saponification of dead bodies in the U. P. and describe the findings in 6 out of 12 bodies studied. Saponification occurs in from 7 to 35 days, and the climate of Lucknow is more favourable to it than is that of Agra. Chemically, the saponified substance was found to consist of lime, soap, free palmitic and stearic acids, unsaponified matter and ash.

With regard to *poisons*, P. B. Mukerji records a case of chloroform poisoning by the oral route in a child of 12 who recovered under vigorous treatment. Major Clive Newcomb notes an interesting point in connection with aconite poisoning. A question was raised in court as to whether the tingling and numbness produced by aconite would not be sufficient to stop the victim from going on eating the sweetmeats or curry containing it, but as Major Newcomb shews, it takes some 10 minutes for the tingling to set in, and half an hour for full numbness to develop. He also comments on the common use by railway robbers of dhatura, administered in coffee, and records a case of fatal poisoning in a young girl with kerosene oil, accidentally

administered in place of quinine. H. C. Gupta records a case of extreme tolerance to morphia, the patient being able to take 40 grains hypodermically or 80 grains orally a day.

MISCELLANEA.

Major Knowles and temporary Assistant Surgeon B. M. Das Gupta record the finding of a Bodo as an accidental parasite in the saliva of a case of spleno-medullary leukaemia. The parasite had nothing to do with the disease, and the infection was a transient one. A successful culture was made in Boeck's medium. The same authors also record a study in culture of *Blastocystis* from several different species of animals and man. It is now clear from the work of several authors that *Blastocystis hominis* is a fungus of a high order, allied to the Schizosaccharomycetes, parasitic—according to Dobell—in the gut of almost every human being, and non-pathogenic. Three different modes of multiplication, by binary fission, and exogenous and endogenous spore formation, are described. The chief importance of this intestinal parasite is that it may easily be mistaken by the tyro in the examination of faeces for the cyst of one or other of the intestinal protozoa.

Lieutenant-Colonel W. C. Ross describes the life-cycle of *Herpetomonas* as being entirely different from what is usually accepted, and considers that binary fission does not take place; also that the parasite is a tissue-inhabitant in flies and that conjugation occurs.

Lieutenant-Colonel C. C. Murison comments on the hospital working day; shewing how lax is the state of affairs with regard to recording the date and hour of admissions, a matter upon which questions may sometimes have to be answered in court. He advocates adopting the 24-hour continental time system, and stating whether local time, railway time, etc., is referred to.

MEDICAL MISSIONS IN INDIA.

Dr. Ernest F. Neve writes from Kashmir as follows:—

"In February 1924 Colonel Megaw wrote an important article on 'India in a state of grave emergency' in which he drew attention to the enormous death rate in India from preventable diseases—about 5,000,000 per annum, and the serious diminution in efficiency of the individual worker from the same cause to between 20 and 30 per cent. He pointed out the effect of this on economic conditions. Two months later an address by Colonel Christophers was published which dwelt very forcibly with the same theme. Not only do these appalling physical conditions exist with their terrible toll of suffering, economic loss and death, but the whole matter is inextricably mixed up with ignorance, warped mental outlook and even religious prejudice, such as, for instance, the Hindu attitude towards small-pox.

If, as we believe, good government should ultimately rest on the consent of the governed, how very important from a political standpoint is the good-will which has been and is being gained by the ministrations of medical relief and public health workers in India. In many districts, for one person who knows the chief administrator, the political agent or British resident, thousands and even tens of thousands know the leading doctor, if he is active and in addition to a large central hospital also carries on district work.

What splendid opportunities there are here, not only for medical and surgical aid, but also of dealing with root causes and of influencing the peoples and bearing witness to higher standards of life, healthier and more sanitary environment, a more enlightened mental outlook and higher moral and ethical ideals.

It is very difficult to obtain information as to the percentage of the population of India for which Western

medical aid or indeed any kind of skilled treatment is available. In the more important centres the Indian Medical Service has rendered splendid service on a large scale. The number of Indian private practitioners is steadily increasing, but these resort mostly to the larger towns.

The work of medical missions in India has become increasingly important. Not only are there many large hospitals and extensive district work carried on in many parts of India, but most of these institutions are out with all their power to strike at the causes of disease and to do their utmost for the moral and ethical uplift of the masses.

At the present time there are approximately 300 medical missionaries in India. Of these about 185 belong to the Medical Missionary Association of India, the president of which is Dr. E. Muir of Calcutta. A quarterly journal is published, edited by Dr. R. H. Goheen of Vengurla, with original communications and an up-to-date résumé of current medical literature. One of the most interesting features of this journal is the insertion of reports of the work of mission hospitals. A reference to only a few of these hospitals will indicate the importance and extent of the work; the Miraj Hospital and Medical School, the Women's Christian College at Ludhiana, the Frontier Mission Hospitals of Kashmir, Peshawar, Bannu and Quetta, the Annual Clinic at Shikarpur and the great activities of the Arcot and Neyoor Hospitals. Altogether there are more than 200 mission hospitals in India, some of which are working on a very large scale and many of which are exceedingly well organised and equipped.

India owes a debt to the United States of America for 118 medical men and women, working in these institutions.

The value of this work in these times of inter-racial strife can hardly be overestimated. It is a power making for friendship and eminently constructive.

Probably there is no agency in India at the present time which is more beneficent in its action, and certainly none which does more to demonstrate the nobility of service and to make the ideals of the Christian faith acceptable to the people."

SERVICE NOTES.

Major C. J. Stocker advocates the entire re-organisation of the Indian Field Ambulance, both as regards personnel, equipment and means of transport, of tentage also, to suit it for conditions of warfare on the N. W. Frontier. His article, which is a long and detailed one, and which was published in our issue for last July, is worth consideration by all military medical officers.

Lieutenant-Colonel R. A. Needham, Deputy Director-General, Indian Medical Service, writes as follows:—

"The report on the Lee Commission was published in May and they recommended far-reaching changes in the organisation and administration of the Medical Services in India. They recommended that no attempt should be made to retain the I. M. S. in its present form and new proposals were put forward for the creation of a purely military medical service for Indian troops and for the creation of a series of Provincial Medical Services. These proposals involve military as well as civil consideration and are still under the consideration of Government.* At the September session of the Legislative Assembly, the Government's position was expressed in the following three resolutions:—

* An official communiqué has subsequently been published stating that, in the main, the Secretary of State has accepted the recommendations of the Commission, but that a decision as to the future of the I. M. S. has not yet been come to.

(1) That the following recommendations of the Royal Commission on the Superior Civil Services in India be in principle approved:—

(a) That while the existing system of appointment and control of the All-India Services should, in present conditions, be maintained in reserved fields, the following services operating in transferred fields, namely, the Indian Educational Service, the Indian Agricultural Service, the Indian Veterinary Service, the Buildings and Roads Branch of the Indian Service of Engineers in those provinces in which the two branches have been separated, and the Indian Forest Service in Bombay and Burma, should, so far as future recruits are concerned, be appointed, and controlled by local Governments; (b) that recruitment of Indians for the Services in reserved fields should be increased as recommended; (c) that, having particular regard to recommendation (a), early steps be taken to constitute the Public Services Commission contemplated by Section 96-C of the Government of India Act, and to enact such legislation as may be necessary;

(2) that pay, passage concessions and pensions be granted to the officers of the Superior Civil Services in India approximately on the scale recommended; and

(3) that the recommendations of the Royal Commission regarding the constitution of Provincial Medical Services in Governors' Provinces be accepted in principle, subject to:—

(a) The employment in the provinces of an adequate military reserve; (b) the provision of adequate medical attendance for British officers in the Civil Services and their families; and (c) the further consideration of the conditions necessary to secure an adequate number of British medical recruits for the needs of the Army.

In this connection it is interesting to note that the I. M. S. consists at present of:—

Permanent officers	.. {	European	.. 531
		Indian	.. 148
Temporary officers	.. {	European	.. 4
		Indian	.. 145

Casualties.

Died.

Major E. J. C. McDonald and Major F. W. Cragg.

Resigned.

Capt. B. F. Beatson (granted a permanent commission in the R. A. Force from 7th November 1923); Capt. A. G. Cowper; Lieut. I. C. Robertson.

Retired.

Major-General Sir G. G. Giffard; Major-General C. H. Bowle-Evans; Major-General B. H. Deare; Major-General W. E. Jennings; Major-General J. Jackson; Colonel W. G. Pridmore; Col. Bhola Nauth; Col. V. B. Bennett; Lieut.-Col. S. A. Harris; Lieut.-Col. L. B. Scott; Lieut.-Col. F. H. Watling; Lieut.-Col. J. J. Urwin; Lieut.-Col. V. E. H. Lindesay; Lieut.-Col. W. H. Kenrick; Lieut.-Col. P. St. C. More; Lieut.-Col. J. W. Grant; Lieut.-Col. N. W. Mackworth; Lieut.-Col. J. Entrican; Lieut.-Col. J. M. Holmes; Lieut.-Col. E. M. Illington; Lieut.-Col. W. G. Liston; Lieut.-Col. F. A. Smith; Major H. Falk; Major W. P. G. Williams; Capt. P. J. Veale (died on 30th July 1924, after retirement)."

The writer of this rather lengthy review cannot bring it to a conclusion without expressing his gratitude to the many contributors who have so kindly, and at considerable personal trouble, helped to make it what he hopes is more of a symposium by different authorities than the work of a single reviewer.

THE PROBLEM OF EPIDEMIC DROPSY AND BERIBERI.*

By HUGH W. ACTON,

MAJOR, I.M.S.,

Professor of Pathology and Bacteriology;

and

R. N. CHOPRA, M.A., M.D. (Cantab.),

MAJOR, I.M.S.,

Professor of Pharmacology, School of Tropical Medicine and Hygiene, Calcutta.

Introduction.—Up to the present time, the general consensus of opinion has been that the two closely allied diseases, beriberi and epidemic dropsy are caused by some deficiency of an essential substance (vitamine) in the diet. We look upon these two diseases as belonging to a group syndrome, where the three main signs are œdema, hypertrophy followed by dilatation of the heart, and peripheral neuritis. In epidemic dropsy usually only two of these signs are present, i.e., the œdema and the effects on the heart, and in dry beriberi there are cardiac lesions, marked peripheral neuritis but little or no œdema. Between these extremes, there are overlapping cases where these three signs vary in extent. We can therefore compare it to a syndrome like asthma where there are diverse poisons all producing the characteristic signs of this condition, viz., bronchial spasm and turgescence of the mucous membrane, but in varying extent; so that we get cases of almost pure bronchial spasm and others largely with bronchial turgescence. As will be seen later, we consider the cause of this syndrome of beriberi to be due to certain poisons elaborated in the food which is improperly stored; thus we have seen these symptoms and signs produced by rice, by the exclusive use of tinned provisions (Mesopotamia and Calcutta), and in Labrador it is stated that eating dried codfish causes this disease. The upholders of the rice theory immediately advance the argument; did these people eat rice, say as puddings, or was the flour adulterated by the cheaper rice flour? There is no need for this refinement, as we know that provided the same proteins or amino-acids are present, the decomposition of an amino-acid-like tryptophane to indol is not the exclusive property of a single proteid or single species of bacteria. We can safely say however that the vast majority of cases seen in clinical practice occur amongst those whose main article of diet is rice.

The first point that has to be settled is whether the disease is due to eating rice or not? The following objections have been raised against the rice theory in Castellam's "Text-Book on Tropical Medicine," (1919), page 1677.

(i) "Beriberi may occur in people who do not feed on rice. We have seen an epidemic amongst officers on a man-of-war." Against this objection we may state that beriberi occurs—though rarely—amongst British troops who are not rice eaters, but who take a certain amount of rice as rice puddings or in lieu of potatoes, as in Mesopotamia during the war. The rice issued is frequently diseased, e.g., on the R. I. M. S. *Investigator* in the Persian Gulf. Moreover under these conditions there is a large amount of tinned provisions used as food.

(ii) *The geographical distribution.*—"In populations eating the same kind of rice, some suffer from beriberi and others do not." In Bengal, epidemic dropsy is a disease of the middle class Hindoos, whose diet is mainly rice. The neighbouring Mohamedan population, although eating the same rice, take a smaller quantity of it owing to the inclusion of bread, meat, etc., in their diet. Again, the poorest classes live largely on a small grained rice of a coarse quality, but freshly milled, and rarely suffer from this disease.

(iii) "Tamil coolies in Ceylon do not get beriberi though they suffer from this disease in the Straits Settlements. In both countries they are mostly supplied by the same kind of rice, Rangoon rice." Our experiments show that a hot moist climate is necessary, such as occurs in Calcutta during the middle of July to September for infection to take place in the rice, thus explaining the peculiar distribution of the disease.

(iv) "People recovered from beriberi go back to their usual rice diet without suffering from the disease. Thus in the Malay States the mortality is only 20 per cent. therefore 80 per cent. of the sufferers recover. Do these people change their diet?" Our contention is that the disease is due to infection of the grain and the formation of poisonous bases. As long as healthy grain is eaten no disease occurs. Conversely as soon as the supply of diseased grain is exhausted, they then live on healthy grain and without any change in the diet recover, irrespective of avitaminosis.

Now having considered that we have satisfactorily answered these objections raised by Castellani against the rice theory, and moreover that all the ætiological factors point to the same conclusion, we can safely assert that in the vast majority of cases, both beriberi and epidemic dropsy are diseases produced by eating rice.

Eijkman, in 1897, showed that prisoners fed on red unpolished rice escaped the disease, whilst those fed on white polished rice were very apt to suffer from beriberi. Both he and Voderman considered that this was due to a loss in the protection of the grain. Fraser however failed to produce beriberi in prisoners fed on polished rice. The difference between these two forms of grain is that white rice is deprived of the peripheral layer during the milling processes.

The works of Eijkman, Braddon, Vedder and Chamberlain have made it sufficiently clear that beriberi is caused by eating polished rice and is prevented by eating unpolished rice.

Casimir Funk described a base that was present in the pericarpal layers, a diamine belonging

* Received for publication, 21st November, 1924. Being a paper read before the Medical Section of the Asiatic Society of Bengal on the 12th November, 1924.

to the pyrimidine group and of the following constitutional formula:—

This base is soluble in water, alcohol, dialyzable and can stand heat up to 130°C.: it is present in the proportion of 0.1 gramme per kilogramme of rice polishings:—the term polishing is often held to include rice bran and the polishings. Funk regards this base as an essential to the nervous tissue metabolism, and if not present in sufficient quantities, the nerves break down and as a result beriberi occurs in the individual. In 1917, Chick and Hume showed that in order to keep a person in health there must be (1) a proper supply of proteins, carbohydrates, fats, salts, and water, (2) an adequate amount of vitamins. These vitamins have not been isolated in a pure state in order to determine their chemical composition, but some are water-soluble, others alcohol—and others fat-soluble. They can stand a temperature up to 100°C., but are destroyed at 120°C. The vitamine of importance in beriberi has been named the anti-neuritic or anti-beriberi vitamine, the first includes the polyneuritis of fowls. The vitamine theory in some form is universally accepted at the present time to explain the cause of these so-called deficiency diseases.

Manson brought forward the hypothesis that a germ may be present in the soil, house, or ship, and under certain conditions of temperature and moisture may grow and produce toxins which when ingested cause the disease. Moreover, this germ may be carried by man from place to place. He also pointed out that the disease clings to ships, and appears year after year when the tropics are reached. In support of this theory he points out (1) that when patients are removed from an epidemic area they at once begin to recover; (2) he quotes Hirota's observations, that 52 infants nursed by beriberi mothers showed signs of the disease and did not improve when treated medicinally, but when taken from these mothers and placed with a wet-nurse or on artificial foods rapidly improved. He rightly points out that these children must have been poisoned by some chemical substance and not infected with a germ. But of course the germ producing the toxin might be in the mother's body.

Yamagriva considers beriberi to be caused when the rice is improperly stored or preserved as it occurs even when this rice is well boiled. Bradon ascribes the disease to the ingestion of a poison found in the rice which is the result of a specific product of some organism, epiphyte or parasite, but he does not believe the disease to be due to the ingestion of the organism.

This briefly is the present position of the beriberi problem.

(a) The majority of observers consider that it is a deficiency disease due to the lack of an essential vitamine.

(b) A few consider that it is due to a poison produced in the grain by some organism or by defective preservation or storage.

Our work commenced with the production of certain poisonous bases produced in an amino-acid broth by the *B. dysenterica* (Shiga) 1922. Again in the same year when working on lathyrism which is caused by eating *kesari dal* (*Lathyrus sativus*), we found certain bases, not alkaloids, by which we were able to produce the disease in animals. On going away on furlough, Colonel Megaw handed us over the results of his clinical and statistical enquiry into the causation of this disease, which he has now published (1923). Naturally as we had been working at these bases, the first thought that occurred to us was whether we were dealing with a similar problem to ergotism, where alkaloids and bases can be produced by the *Claviceps purpurea* from the proteids of rye; these are able to cause vaso-constriction (gangrene) and neuritis sensory (anæsthesia). In beriberi, which is due to rice eating, the symptoms caused are due to an increased capillary permeability (œdema) and a neuritis motor (paralysis). The problem that lay before us was to identify the diseased rice from the healthy, to isolate the organism producing the disease in the rice grains, and to separate the bases, and reproduce experimentally in animals the symptoms produced in man. On the other hand we could not totally disregard the vitamine theory, when such skilled workers as Hayden, DeSilva, Chick, Hume, Moore and Webster had made this theory acceptable to the medical profession. We hoped by our experimental data to harmonise these two opposite views on beriberi, and to show that when the pericarp is removed by polishing, there is lost, not only the mechanical protection of the grain, but also valuable antagonistic substances. Under certain conditions of temperature and humidity, especially if rice is stored in infected godowns the rice rapidly becomes diseased. This diseased rice contains bases that cause a rise of limb volume with a fall of blood pressure, indicating œdema, increase in the amplitude of the heart-beat explaining the hypertrophy, and a rise in intra-ocular tension, the cause of glaucoma in epidemic dropsy.

If we consider beriberi to be produced in a similar way to asthma we will have three things to consider:—

- (1) The nature of the poisons produced.
- (2) The endocrine mechanism.
- (3) The state of the nerve endings that receive these poisons.

During the last three years we have had several difficulties to contend with before we were able to complete this work. In the first place when we commenced working on rices, that caused epidemic dropsy we were able to show the existence of substances that produced a rise in the limb volume and an increase in the intra-ocular tension, but when working on Burma rice we were hardly able to demonstrate the presence of these bases, and it was a long time before we realized the difference in the chemical composition of these two rices. Again, we found that animals varied

widely in their reactions towards these poisons: this meant the investigation of the causes of susceptibility, and our results were published in *The Indian Medical Gazette* for July 1924.

The neurotoxic principle again proved a stumbling block until we discovered it was alcohol-soluble and not water-soluble and moreover that it paralysed the para-sympathetic. The last difficulty to be overcome was the production of these bases in sterile media from laboratory cultures. For a long time, when growing the cultures aerobically, we were only able to produce the water-soluble bases. It was not until we realized the anaerobic thermophilic nature of rice decomposition, that we were able to produce the neurotoxin by raising the incubator temperature to 50°C. and making the cultures anaerobic.

THE INFLUENCE OF THE SUBSTRATE.

Before we can appreciate the differences in the different grades of rice, we must be able to judge the character of the fruit. The usual classification adopted by the market has been to name a rice after some prominent character, e.g., *Patni*, from the centre of export; *Peshawari*, because it was handled by up-country merchants; *Basmati*, fine flavoured, etc. A better idea of the quality of the rice can be obtained by the following description which we have evolved in trying to understand, how rice caused epidemic dropsy or beriberi.

The texture of the fruit. By the water test, two main varieties are seen by looking at the grain in water—

(a) Coarsed grained fruit: the grains may be short and plump such as the Burmah rice, or long and plump like the *desi* or indigenous rice, e.g., *Ashu*, *Nagra*, *Patni*. The grain has a horny-like appearance, and is known to be not very digestible, but sweeter. These rices are new, sell at from 5½ to 6 seers to the rupee, and are eaten by the poorer classes. When allowed to season, they give a very sweet rice which is mainly used for *payesh* (rice cooked in milk).

(b) Finer grade rice: the fruit may be long and fine like the *dadhani*, or long and medium such as the *Peshawari* and *Kaminibhog*, etc. The grain is semi-translucent and the better the grade the more waxy is the appearance. These rices are more digestible and command a higher price, from 3½ to 1 seer for the rupee, and are usually eaten by the middle and upper classes. When allowed to season, this class produces a very digestible rice, which is eaten with curry, *dal*, etc.

The quality is also dependant on the crop. Thus in Bengal there are two main crops in the year—

(i) The *aus* or early crop is sown broadcast in April, and is reaped during July and August and September. It is generally regarded as being poorer in quality, very indigestible and causing diarrhoea. It is eaten by the poor, and is also used as food for animals.

(ii) The *aman* or winter crop is the better crop of the year: the rice is transplanted in June, July and August and is harvested in November and December, it is spoken of as the *chotan aman*. This is the rice that is largely eaten by the middle class Bengali families. The *boran aman* is a coarser kind of rice sown broadcast in the beds of the *jheels*, and in very low-lying land in May, and gathered in December and January.

The *boro* or spring rice is far less important than the above mentioned crops and rarely comes into the markets of larger towns. We have therefore two grades of rice—

(a) The coarser rice: more horny in appearance, more indigestible and eaten by the poorer classes owing to its cheapness. It is largely derived from the *aus*, *boran aman* and *boro* crops—and as we will see later this rice is concerned with beriberi.

(b) The medium and finer grades: more waxy in appearance and more digestible and eaten by the middle and better classes. This is derived mainly from the *chotan aman* crop, and if diseased causes epidemic dropsy.

In Bengal, epidemic dropsy is a disease of the middle class Bengali, whose main article of diet is the medium grades of rice; whereas the Chinaman, who lives on the highly polished coarser rice, suffers from beriberi. The distinction between the two diseases is very fine; in epidemic dropsy, oedema and the effect on the heart are prominent, whilst glaucoma and a slight degree of neuritis is sometimes seen. In beriberi, the neuritis and the heart signs are always marked, but the oedema may or may not be present and glaucoma is rare. The poisons produced in the two substrates cannot be identical in amount, but in extreme cases, i.e., dry beriberi and epidemic dropsy without loss of knee-jerks, the poisons can be readily separated in the rices, but there must necessarily be a good deal of overlapping when the substrates are like each other in chemical composition, e.g., when the medium grades approach the coarser quality.

THE PREPARATION OF THE RICE FOR THE MARKET.

(a) The husks are prepared for removal from the *paddy* or *dhan* in one of the three ways—
(i) *Atap* or sun-dried rice, is prepared by soaking the paddy in cold water for 24 hours, and then the grains are dried in the sun by being spread out in thin layers on cemented or specially prepared platforms, hence the name *atap* or sun-dried. This rice is generally eaten by orthodox Brahmans, widows, and at certain festivals, for the Brahmans are not allowed to eat food other than that cooked by their own hands. This method of preparation of the rice does not destroy the enzymes of the grain. (ii) *Balam* rice consists of *paddy* which is husked after hot water

has been sprinkled on it. The water inflates the grain, and when dry facilitates the removal of the husk. The heat is not sufficient to kill the enzymes or coagulate the proteids, but avoids the number of hours that are required to swell the grain by simple steeping in cold water. (iii) *Siddha* or parboiled rice is prepared by soaking the *paddy* in large vessels and then the water is brought up to the boil. The parboiling kills most of the enzymes, and coagulates the surface proteids in the grain. This parboiled rice is dried on platforms before it is husked. Rice from over-steeped *paddy* is dark in colour, and when overboiled is coarse in appearance, and in the milling it is often broken up into fragments. It will be seen that the better and medium grades of rice used for ceremonial purposes (*atap*) or otherwise (*balam*) are generally steeped in cold water or hot water respectively in order to preserve the enzymes of the grain and allow the seasoning processes to follow when the grain is properly stored. The medium and coarser grades are more often parboiled as it is easier to separate the husks.

(b) The removal of the husks may be carried out in two ways—(i) *Anchatta*, by hand: this is generally done in the villages with a wooden pestle and mortar, or by it being beaten on a platform with a wooden beam (*dhenki*). The *paddy* is stored as such, and, when required, a small amount is taken out, say a 2 to 4 weeks' supply. The husks are prepared for removal, and the hand pounding leaves a good deal of the pericarp on the grain. During this process many of the grains are broken, and *atap* with entire grains sells at a higher price than the *siddha* or parboiled rice, although made from the same *paddy*. (ii) *Kalchatta* or machine removal is carried out where mills are available in the large towns. In the first place the hulls are removed by passing the grain through milling stones, screens, and winnowing machines. The kernels are then decorticated, and the outer cuticle with much of the gluten layer of the grain and the embryo are removed: this constitutes the rice bran or meal. This rice is known as unpolished rice.

(c) The polishing process is the final process which the grain undergoes. The polished grain is placed in rotating cylinders of wood and wire gauze, the surface of which is covered with soft tanned hide. In this process a film of gluten and starch cells is removed, and the fine powder thus obtained is technically called rice polishings: the polished grains are then screened in various grades and sizes.

These terms such as *atap*, *balam*, etc., are not the names of different rices but of various processes which the grain goes through before it arrives on the market.

We are now in a position to appreciate the fact that parboiled polished rice is the most dangerous type of process to subject rice to, because all the living cells and enzymes of the grain

have been killed by the heat, and the machine-milling and polishing has removed the embryo and the delicate starch cells, so that raw surfaces are exposed to the attack of bacteria and fungi. This rice, as we shall show later, when stored under favourable conditions of temperature and humidity is likely to become diseased, and so produce epidemic dropsy or beriberi. In villages the removal of the husk is facilitated by sun-drying or steeping, the husk is removed by hand, which leaves much of the pericarp and the whole of the gluten layer, only small quantities are prepared at a time so that a sufficient time is not allowed to elapse for gross invasion of the grain.

These factors all combine to explain the comparative immunity of the villagers to epidemic dropsy.

The seasoning of the rice.—Everyday experience has shown that new rice is indigestible, but if kept for some time—six months or more—the rice becomes more digestible and sweeter. Thus the rices can still further be subdivided into—

(a) New rice which is more indigestible, cheaper, and is the type usually eaten by the poorer classes and villagers. As a rule no preservatives are added and it is eaten soon after being turned out from the mills. Hence these diseases are not seen amongst persons eating this rice, as there is usually not sufficient time for it to get diseased. With imperfect storage in godowns or in transportation, this parboiled highly polished rice rapidly becomes diseased as no preservatives are added, and then beriberi is seen amongst those who consume the rice under these conditions.

(b) *Seasoned rice.*—The better classes demand a rice for one of its two qualities, (i) digestibility, (ii) sweetness. The seasoning of rice takes some months in storage to effect the hydrolysis of the insoluble proteids and carbohydrates into the more soluble proteoses, peptones and sugars. These characters are brought about mainly as the result of the hydrolysis of the proteids and carbohydrates by enzyme action. Such rices are either sun-dried or steeped and never parboiled, although they may be highly polished. Thus the Marwaris eat this rice mainly as *kher* (i.e., rice boiled in milk and eaten as a porridge) and so require the rice digestible and sweet, whilst the Bengalis and Mohame-dans who eat their rice with *tarkari* or curry do not require it to be sweet, as the latter flavour would interfere with the high seasonings of the curry. Such rices are carefully selected and preserved from bacterial or fungal attack. Thus the middle grades of rice eaten by the Bengalis who suffer from epidemic dropsy are invariably parboiled and milled. As it is a cheaper grade proper preservatives are not added, so that the grain is very apt to get diseased if improperly stored.

Chemical tests.—It is well known that the cheaper rices are more indigestible but sweeter, as has been shown by numerous analyses. To illustrate this point we selected two samples of healthy rice and submitted them to Dr. N. L. Bannerji for chemical analysis.

PLATE I.

Showing the appearance of healthy and diseased rice by the water test.

The five grains above are diseased Burma rice and the lower, healthy rice. In polished grain the attack may come from the surface.

Burma rice, healthy, yellow and horny in appearance.

Middle grades, waxy in appearance.

which he kindly carried out for us. The results were as follows:—

Name of the Rice.	Kjeldahl.	Protein % = N X 6.25.	Amino N. * Van Slyke.	Crude Fibre.	Cane Sugar.	Reducing Sugar.
Burma Rice.	1.001%	6.25%	0.935%	0.63%	0.08%	0.02
Dadkhani Rice.	0.966%	6.03%	0.91%	0.22%	nil	trace.

* Van Slykes, estimation of amino nitrogen was performed after complete hydrolysis of the rice by means of 20 per cent. HCL and the solution was afterwards practically neutralised and acted upon by HNO₂ for 5 minutes with shaking.

It will, therefore, be seen that the Burma rice contains more crude fibre and more sugar than the *dadkhani*, a good grade rice.

DISEASED RICE.

When rye is infected with *Claviceps purpurea* the grain turns a black colour and the diseased grain can readily be made out. With rice on the other hand, the colour is not altered but the grain becomes opaque and this is not noticed by the ordinary individual. To detect this diseased rice the following tests have been employed by us:—

- (1) The water test.
- (2) Section of the grain.
- (3) The chemical separation of the water,—and alcohol-soluble bases.
- (4) Pharmacological tests.

(1) *Water test.*—(Plate I). Amongst people whose main food is rice, it is astonishing how few of them are able to recognise diseased rice. Amongst the various medical men to whom we have shown this test there was not a single individual, who had seen it used to test the condition of the rice. We are indebted to a rice merchant for showing us the test, which is employed by the trade. The test is simple enough, and consists merely of throwing a small quantity of the rice into a glass or brass dish, which contains water and then looking at the various characters and defects of the grain. If the grain is allowed to stand too long in the water, the fruit becomes swollen and opaque, but this takes some ten minutes or more, so that there is ample time to study the rice.

The first character to look at is the size of the grain; the coarser rices are short and plump, and the medium grains longer and thinner, whilst the best grains are generally rather long and fine. The coarser rices have a horny appearance, the medium and finer grades are waxy in appearance, and the longer the seasoning the more waxy is the character of the grain. Fruit that has been for a long time stored in the husk or over-steeped is often tinged with a yellow or reddish colour. Again one can easily see whether the rice has been polished or unpolished by the presence or absence of the sub-pericarpal layer.

(a) When the fruit is diseased the grain becomes absolutely opaque. In coarser rices the colour is slightly yellow, whilst the medium grains have a dead white plaster-like colour. In the polished rice, the invasion may be from the surface of the grain, or from the embryonic site. In parboiled unpolished rice the attack is usually from the embryonic side. The grain may be attacked by various fungi which will be described in detail later, but for the present we will only consider bacterial infection. This usually occurs from the embryonic site, or through injuries inflicted during the polishing processes of the grain. Under these conditions the disease of the grain is not so easily recognised unless this water test is used to demonstrate the increase in the opacity of the grain.

(b) Fungi attack the rice during the monsoon months of July, August, and September, when the temperature is lower but when there is a high humidity present which makes everything damp, e.g., leather gets attacked by a brown, yellow or black *Aspergillus*, the same happens to the rice grain if it is damp, and becomes yellow or brown in colour but the fungus does not invade the grain, and when the grain is attacked the rice merchants in order to avoid a loss repolish the rice. During this brushing process the grain, being more friable, is apt to break into small fragments or blocks, and these are technically known as brushings. The brushings are mixed with healthy grain, and sold to the public. This simple test tells us the character of the fruit, whether polished, unpolished, healthy or diseased, or whether it is mixed with brushings.

In all the cases where we have been able to test the rice actually eaten by the affected epidemic dropsy families, the larger portion of the grain has been attacked by this bacterial disease. In some families we failed to find any infection of rice, as they only bought small quantities at a time from the retail merchants.

In some samples of rice kindly sent to us by Major J. Jolly, I.M.S., from Burma suspected of producing beriberi in jail populations, one sample consisted of a medium grade rice which was unpolished, but was extensively adulterated with diseased coarse grain Burma rice; the other samples were Burma rices in which almost every grain was found to be diseased.

(2) *Sections of the rice with white opaque grains.* show a liquefaction of the starch cells (Plate II). This liquefaction may commence from the surface in polished grains or from the embryonic site. It is, however, necessary to differentiate this from the burrows of the larvae of weeviles. When the grains are badly diseased, the rice can be crushed up into a fine powder by the fingers. In future we will speak of such grains as diseased rice, and where no such change can be seen as healthy rice.

(3) *Chemical separation of the bases from diseased rice.* In every experiment we carried out on diseased rices, we used the water test to

see whether the grains were really diseased or not, and the rice was always obtained from the actual food supply of infected patients. We also tested a sample that was obtained in the market similar in quality, but not showing disease by the water test: this acted as our healthy rice bases, i.e., as control. In cases where we obtained rice which appeared quite healthy and obtained from persons suffering from epidemic dropsy, we found that the original stock had been exhausted and this sample was from a new source of supply. During the last three years of experience on the extrac-

in a litre of water and kept overnight in the cold room at 4°C. Next day it is filtered and treated with the same bulk of water and this is repeated three times, the filtrates being kept in the cold room to prevent bacterial changes. A sufficient quantity of sulphuric acid is added to the total filtrates to make it a 5 per cent. solution. The bases are next precipitated with phospho-tungstic acid and filtered. The precipitate is washed and dissolved in diluted acetone (two parts of acetone to 3 parts of water) and then decomposed by baryta water and filtered. The barium is removed from the filtrate by CO_2 , and finally any trace is precipitated by a few drops of sulphuric acid. The solution is then filtered and neutralised by dilute sodium carbonate. Then evaporated to dryness under vacuo. This constitutes the total

PLATE II.

tion of these bases from diseased rices, our chemists—Mr. N. R. Chatterji, M.Sc. and Mr. A. T. Dutt, B.Sc.—now employ the following processes, and we may here take the opportunity to express our thanks for all the work and energy they have expended on this research. Without their co-operation we would have been still in the blind stages of feeding animals on polished and unpolished rices.

The bases extracted can be divided into two categories—

- (a) Water-soluble bases.
- (b) Alcohol-soluble bases.

(a) *The water-soluble bases* were extracted as follows:—One kilo of coarsely powdered rice is soaked

water-soluble bases from epidemic dropsy or beriberi diseased rices.

The total bases are then fractionated in the following ways:—

(i) They are dissolved in weak sulphuric acid, and precipitated by silver nitrate. This precipitate constitutes the purine fraction and the silver is removed by dilute hydrochloric acid.

(ii) The filtrate from the purine fraction is treated by an excess of silver nitrate and a few drops of baryta added when a brown precipitate occurs, the histidine fraction. The metals are removed from the precipitate by hydrochloric and sulphuric acid.

(iii) The filtrate from the above is now treated by an excess of baryta and a further precipitate occurs, "the argentine fraction." The barium is removed by sulphuric acid.

(iv) The solution from the above is made free from barium by blowing CO_2 through the solution and then

by a few drops of dilute sulphuric acid, and any trace of silver by hydrochloric acid. The filtrate is evaporated to dryness in a vacuum, "the lysine fraction."

(b) *The alcohol-soluble bases.* The crushed rice was soaked with rectified spirit in a percolator for 48 hours. The extract was then drawn off and the alcohol recovered by distillation. The residue was extracted

kindly examined ophthalmoscopically six cases, that were recently under our care, noticed marked cupping of the disc in all the cases. Graph V shows the effect of the lysin fraction of the bases of beriberi rice on the excised heart of a rabbit. There is at first a very marked augmen-

GRAPH IV.

Showing the pharmacological effect of total bases obtained from different rices.

with petroleum-ether to remove fats and oily matter. Then rubbed in a mortar with absolute alcohol and was then filtered, and the alcohol removed by evaporation. The residue was dissolved in dilute phosphoric acid and utilized for tests.

These bases were then submitted to pharmacological tests.

(4) *Pharmacological tests.*—Graph IV shows the effects pharmacologically obtained from the total water-soluble bases of the different rices : (i) From healthy rice there is no effect seen. (ii) With the bases from epidemic dropsy rice, showing marked bronchial constriction, a slight fall in blood pressure followed by recovery, but the important point to notice is that there is a marked rise in limb volume which is delayed and is not due to a vascular dilatation. (iii) Shows the effect of the bases from beriberi rice; here the bronchial constriction is much less marked, and the limb volume rises only as a result of the general vaso-dilation, which is consequent on the fall of blood pressure. (iv) The intra-ocular tension with the bases from epidemic dropsy rice (shows a slight rise). Colonel Coppinger who

tation of the heart beat, which is soon followed by a diminution of the beat, and in a very short time the heart almost ceases beating.

GRAPH V.

Showing the effect of the bases from the lysin fraction (beriberi) on the isolated heart.

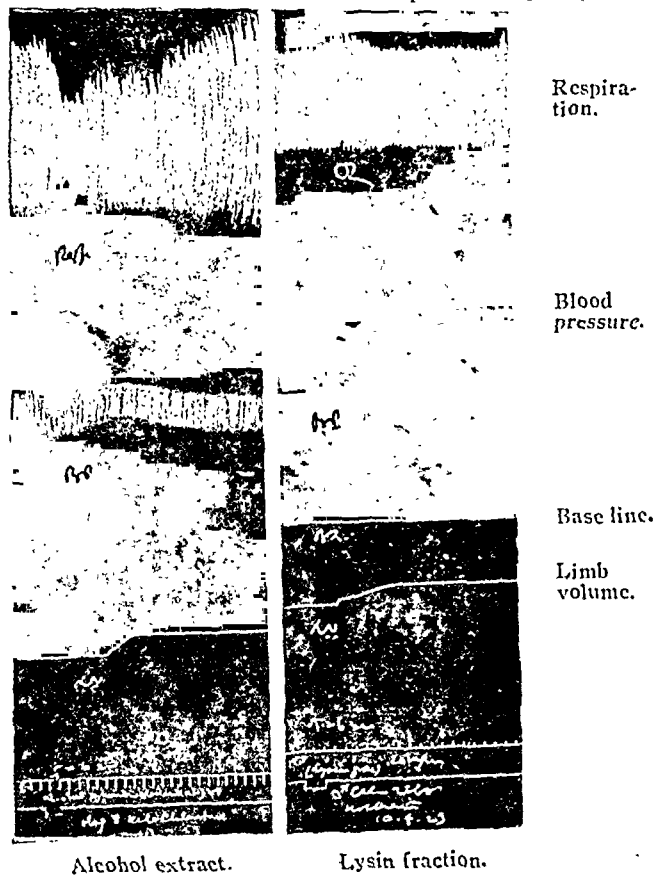

Lysin fraction (beriberi rice).

Graph VI shows the effect of the alcohol extract of epidemic dropsy rice. In the alcoholic extract there is a bronchial relaxor, which causes a great augmentation of the heart beat; the limb volume

risers and remains raised for some time. The lysin fraction of the water-soluble bases contains a substance which causes bronchial constriction, a marked rise of blood pressure which is sustained, and a rise in limb volume following more slowly after the rise in blood pressure.

GRAPH VI.

The alcohol and lysin fraction of epidemic dropsy rice.

Graph VII shows the effect of the bases obtained from beriberi rices. (a) Shows the effect of the histidine fraction: here we have a bronchial constriction effect, a fall of blood pressure, and no alteration in limb volume. (b) Shows the effect of the lysin fraction: here there is a very marked and sustained rise of blood pressure, a marked relaxation of the bronchial muscle, a marked rise in intestinal volume and movement: in spite of the rise in blood pressure, the limb volume is not altered. (c) Shows the normal effect of pilocarpine on blood pressure and respiration, i.e., a fall of blood pressure and bronchial constriction. The bases obtained from the alcoholic extract of beriberi rice completely inhibit the effect of pilocarpine.

We have therefore in these rices the following pharmacologically active bases. The total water-soluble bases from epidemic dropsy rice produce bronchial constriction and a rise in limb volume and this effect is not seen with the water-soluble bases from beriberi rice.

In the water-soluble fractions the active bases are as follows:—

(a) Histidine fraction, more marked in epidemic dropsy rice, a substance like histamine which causes a fall of blood pressure and marked bronchial constriction.

(b) Lysin fraction, more marked in beriberi rice; a very powerful base which causes a rise of blood pressure, bronchial relaxation and on the excised heart, first stimulates and then arrests the heart beat.

In epidemic dropsy rice there is no bronchial relaxation and there is a rise in limb volume.

In the alcohol-soluble bases:—

(a) Epidemic dropsy rice bases augment the heart beat, cause bronchial relaxation and a rise in limb volume.

(b) In beriberi rice there is no effect on respiration or blood pressure, but paralysis of the parasympathetic as shown by the blocking of the normal action of pilocarpine.

You can now realise our first difficulty when we had these varying reactions to contend with in these diseased rices, as we had not realised the difference in their end-decomposition products. These bases are sufficient to explain the neuritis, gastro-intestinal, cardiac, and other symptoms of the two grades of rice; epidemic dropsy rice has more water-soluble bases producing oedema, whereas beriberi rice has more of the neurotoxin.

THE CAUSES OF DISEASE IN THE RICES CONCERNED.

We have already seen how the milling and polishing processes damage the grain and render it liable to attack at the embryonic site and from the surface when the rice is highly polished (see Plate I). There is another factor that sometimes helps in the disease of these grains, and that is the infestation of the rice by the larvae of various weevils and moths.

To show the cause of the disease in the grain we adopted the following methods of investigation:—

(i) Sections of the grain.—The technique which we adopted was one of these two methods.

In the first, the grain was boiled in a 3 per cent. acetic acid for a few minutes, then put into acetone for $\frac{1}{2}$ to 1 hour, dried, and then put into an aqueous solution of glycerine and kept in the incubator for 3 or 4 days until the rice grains were sufficiently softened for sectioning, transferred direct into the paraffin bath for 2 hours, and then cut. In the second method, the grains were put into cellulose acetate in acetic acid overnight, washed in dilute acetic acid and then in water for half an hour, transferred into 50 per cent. alcohol for 1 hour, then into absolute alcohol for 1 hour and finally to the paraffin bath for 2 hours.

Sections were cut and stained by Möller's method for spores, and counter-stained with Manson's methylene blue. We are indebted to Dr. S. Bose, Botanist of the Carmichael Hospital, Belgachia, for showing us the technique for cutting these grains of rice.

Sections of the diseased grain showed the constant appearance of spores and less commonly of bacilli inside the rice grains (see Plate III). Occasionally we encountered a smut of which the spores were seen at the surface of the grain.

(ii) Cultures from the diseased grain.—The technique adopted by us was to immerse the rice grain for

half an hour in pure carbolic acid in order to sterilise the surface. The carbolic acid was washed away by absolute alcohol, and the alcohol removed by sterile water. The grain was then broken into two, and planted with the broken surface downwards on agar, and a growth obtained of a spore-forming aerobe. No growth occurred when an unbroken rice grain thus treated was placed on the agar; showing that the bacilli were lying inside the grain. We found that boiling in 40 per cent. formaldehyde solution at 58°C. under vacuo sterilised the whole grain; the same happens when 1 in 1000 HgCl solution is used.

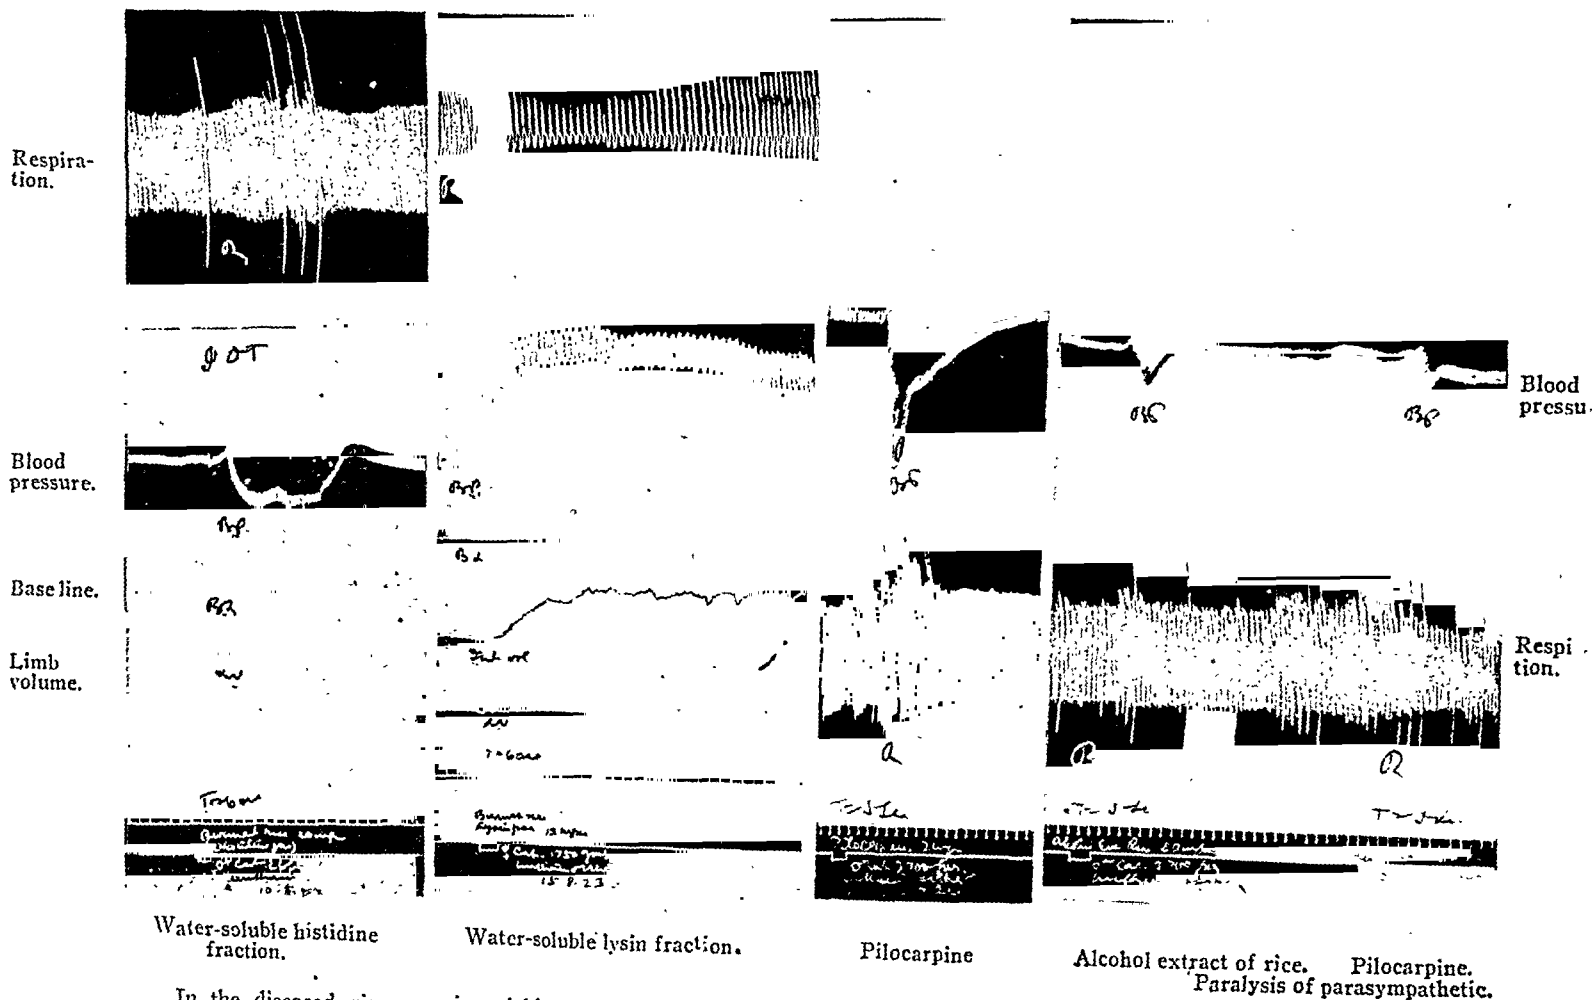

(iii) We next ground up both healthy and diseased rices and the flour from these rices on an agar plate.

and at 50°C. It therefore appeared to be a facultative anaerobe as well as a thermophilic bacterium.

Colonel Harvey, I.M.S., has directed our attention to the possibility of its living in symbiosis with an anaerobe and we are very grateful to him for this suggestion. But at present we have not been able to verify this point by growing the organism from a single bacillus. On agar it forms a white dry wrinkled growth, and on potato a copious white growth. On serum agar it forms a white wrinkled growth and in 2 to 3 days the medium becomes liquefied; until finally the whole slope is digested. Gelatine stab cultures show a marked area of liquefaction. Solid rice media is liquefied in 2 to 3 days. Litmus milk at first turns acid and then white,

GRAPH VII.

Rice eaten by persons suffering from beriberi—the fractions obtained from the water- and alcohol-soluble.

In the diseased rices we invariably found the presence of a bacillus of the *vulgatus* group which we will describe in detail later. In the healthy rice this bacillus was also very frequently encountered. Besides these bacilli, we almost invariably grew colonies of *Aspergillus* of green, white, brown and less commonly of the black variety; a *Rhizopus*, probably *oryzae*, was less frequently seen, and still rarer a *Mucor*. In all the plates there were numerous colonies of yeasts.

The organism isolated had the following characters.—It was a bacillus about 2.7μ long and 1μ broad with rounded ends. It was a spore former; the spore was central in position and did not bulge the sporangium. It was a Gram positive organism, and stained well with all aniline dyes. The spores retained the stain well by Möller's method.

Cultural characters.—It grew well in the presence of air as well as under anaerobic conditions, at blood heat,

owing to the formation of leucobases, and finally the casein is digested.

Sugar reactions.—No change in lactose and dulcitol, but glucose, saccharose and mannite are made acid and then the litmus is converted into leucobases.

Relation to heat and chemicals.—Infected rice when boiled in sterile water for $1\frac{1}{2}$ hour, and then inoculated on agar plates gives the characteristic growth of this bacillus, showing that the spores are not killed during cooking of the rice. The spores require a temperature of 115°C . for 10 minutes to be destroyed.

We have therefore an organism of the genus *Bacillus* belonging to the *vulgatus* group, which is found both in healthy and diseased rice, but it is present only inside the grain in diseased rice, and not in the interior of the grain of healthy rice. It happens to have an intense proteolytic.

PLATE III.

action, and is therefore capable of producing various decomposition products from the proteins of the rice grains. What we desire to make perfectly clear is that we do not claim specificity for this organism. What we have found is that the organism has been demonstrated inside diseased rice grains, and that it has an intense proteolytic action on rice proteids. Whether it is the *only* organism of this large group of spore-forming aerobes that can attack the grain and produce these poisonous bases, we are not in a position to state definitely. In agricultural bacteriology, many of the decomposition processes are commenced by aerobes and completed by anaerobes; whether such a symbiosis exists in the rice decomposition we as yet have not been able to discover.

FACTORS INFLUENCING INFECTION OF RICE.

The rice merchants well know that rice is very apt to decompose in one of these two ways, depending on the moisture present in the grain—(a) If the grain has its ordinary moisture, it may become white and opaque, or (b) if it has been damped with rain, bilge water, etc., it is apt to become mouldy. The season of the year which is most favourable is during the monsoon months. If we study the meteorological conditions during this period, the results are shown in the following table:—

Month of year.	Air temp. °F.	Daily variations in air temp. °F.	Wet bulb °F.	Humidity %.
May ..	85.7	18.4	78.9	75
June ..	84.5	10.4	79.0	83
July ..	83.0	9.6	80.0	87
August ..	82.4	9.2	79.5	88
September ..	82.6	9.0	78.8	86
October ..	80.0	13.2	73.3	82
November ..	72.4	18.3	65.0	74

It will be seen that the most dangerous months are those of July, August and September, when the mean air temperature ranges between 82.4 and 83°F with an almost constant daily variation of 9°F and the humidity ranges between 86 and 88 per cent. saturation. This keeps the wet bulb temperature constant during the day and night between 78.8° and 80°F. The following experiments were devised by us to prove this point.

(a) Pre-monsoon period, during May and June when the air temperature was about 85°F with a daily variation between 12 and 18°F and the humidity about 75 to 78 per cent. saturation. Selected healthy rice was lightly sprayed with cultures of this *vulgatus* bacillus, and placed in glass dishes 4" deep. One set was exposed to the air temperature and remained healthy, the other set was placed in a galvanised tank containing about 1" depth of water and covered with a thick glass plate. The air here was well saturated and in a week's time every grain of the rice was attacked by this bacterial disease. From this diseased rice we were able to

separate out the water-soluble bases in the histidine and lysin fraction and also the base that cause oedema.

(b) Monsoon-period, during July to September, when the humidity ranged between 86 to 88 per cent. of saturation. Of the rice trays exposed in the laboratory after spraying, all were affected by this bacterial disease. But on the other hand, the trays in the water tank were rapidly attacked by fungi, *Aspergillus*, *Mucor* and *Rhizopus*; these fungi did not invade the grain but altered its colour from a black to yellow, in a short time the grain became sodden and one could detect the odour of alcohol from the yeast fermentation.

(c) Post-monsoon, end of October and November, when the humidity had fallen to 82 to 74 per cent. of saturation. The rice in the trays in the laboratory remained healthy, but the ones in the saturated atmosphere were moderately attacked by this bacterial disease.

We, therefore, see that the main factors in causing this bacterial disease of rice are the constant high wet-bulb temperature day and night, only varying between 78.8 and 80°F in the 24 hours, and the intense humidity of the air between 86 to 88 per cent. of saturation.

THE ARTIFICIAL PRODUCTION OF THESE BASES.

Until we could produce the various bases under artificial conditions we were not in a position to be certain of our results of this investigation:—

From cultures of the rice which had been artificially diseased by spraying it with this organism, and then keeping it under suitable conditions of temperature and humidity, we were able to separate these various crude bases. This test was not however sufficient, as we could not exclude the various other organisms that may have been present in the so-called healthy rice. In order to prove this point, we prepared rice media as follows:—

250 grammes of rice flour, made from medium grades and coarse grades of rice, were boiled for 1 hour in a litre of water. The volume was adjusted to 1 litre, autoclaved for 20 minutes at 115°C. to kill the spores, and then incubated for 2 days at 37.5°C. to prove that they were sterile. Uninoculated flasks were then incubated and kept as controls. The inoculated flasks were inseminated with this bacillus of the *vulgatus* group, and grown aerobically at 37°C. for 10 days. During the incubation the rice media which was solid to commence with was gradually liquefied; and by the third or fourth day was quite fluid. The controls and incubated flasks were treated chemically and the water-soluble bases extracted from them.

The results are shown in Graph VIII. We may point out that this graph is not the result of one observation but of several observations. We have been working on this disease since 1922, and these graphs are the selected results of three years of hard work. The first portion shows the results of 20 mgms. of bases from the uninoculated control. The second portion shows the effect of the bases isolated from inoculated medium grade rice. Here there is seen a histamine-like

effect, marked bronchial constriction and a fall of blood pressure without any augmentation of the heart beat. In the third portion, an inoculated rice of a coarse grade, here the fraction in the lysin portion is more apparent, there is a marked fall of blood pressure but it is rapidly recovered from; the heart beat is augmented and there is marked bronchial relaxation.

Artificially we were able to produce the same toxins in the histidine and lysin fractions. For a long time however we were unable to produce the neurotoxin that paralysed the para-sympathetic because time after time these attempts failed under aerobic conditions. We then changed the

We have therefore been able to produce artificially the bases present in the histidine, lysin and alcohol-soluble fractions in sterile rice media artificially inoculated with cultures of the same bacillus, isolated from diseased rice. Further, they produce similar results upon inoculation into experimented animals.

INDIVIDUAL SUSCEPTIBILITY.

The third difficulty which we encountered during this work was the question of the individual susceptibility of our animals. For a long time we were extremely puzzled to find dissimilar results from the same sample of rice base; one day it would produce a very good effect from our

GRAPH VIII.

conditions, as soon as we realised the high temperature and anaerobic conditions produced in rice that was decomposing in storage. The flasks were inoculated with the same bacillus and grown aerobically at 37.5°C . for three days until the medium was completely liquified, then the surface was covered with sterile vaseline and incubated at 50°C . for seven days. The alcohol-soluble bases were then extracted from the controls and inoculated rice. The fourth portion of this graph shows the presence of a neurotoxin in the alcohol fraction, and it is able to completely block the action of two milligrammes of pilocarpine.

point of view, whilst if tested to-morrow on another animal the same base would be almost devoid of effect. At first we were inclined to look upon these variations as due to alterations in the processes of extraction employed by the chemist, or to deterioration by light, etc., until one day we decided to test two animals simultaneously; when in one we got a very marked effect, whereas in the other the bases were almost devoid of action. This experiment showed that we were dealing with some individual factor in our animals, and this lead us to investigate these individual peculiarities. The results are embodied in a paper by Acton and Chopra (1924).

There are two primary factors involved in toxicity; (1) the amount of poison ingested; (2) the variations in the internal defence mechanism, on which to a large extent depends the production of symptoms. Thus if the amount of poison be large in amount all the individuals involved will be poisoned; e.g., the incidence of epidemic dropsy in a family where every member is attacked; this is purely a question of toxicity. But in a jail population, where only a few prisoners are attacked and where the whole population is eating an identical diet, we are dealing with the susceptibility of the individual, as the dose of poison ingested must be just under toxic limits for normal individuals. When we investigated what constituted this susceptibility, we found it was a very complicated mechanism, which was associated, firstly with the rate of absorption of the poisons from the intestine, then with the defence mechanism of the liver, which dealt with a certain amount of these poisons, and so regulated the concentration in the circulating blood.

Before the poisons can act on the different tissues their rate of diffusion into the tissues is regulated largely by the endocrine secretions. Thus conditions of hypo-adrenia and hypo-thyroidism are favourable for these toxins to exert their maximum effect. The converse condition of hyper-function of these two glands prevents these bases from acting on the tissues. When conditions of susceptibility are favourable large doses will cause the death of these individuals and smaller doses will produce symptoms in them, whereas normal individuals under similar circumstances will either not die, or escape the disease. During the course of our snake venom experiments, Acton and Knowles (1914) noticed that susceptibility was closely correlated with the colour of our animals, i.e., white goats were more susceptible to cobra venom than black goats. Again Bose and Acton (1924) showed that black rabbits showed a greater reduction of blood sugar after injection of insulin than white rabbits, and this in its turn was associated with the amount of adrenalin present in these animals. We are extending these observations to the action of these bases, toxins, etc., the results of which will be published by us in a separate paper shortly. In Graph IX we see graphically how important is this association. In the upper graph is the record of blood pressure and respiration of a white rabbit; we see that $\frac{1}{10}$ of a c.c. of 1 in 1000 adrenalin raises the blood pressure from 70 mm. to 180 mm., whilst tyramine and pilocarpine have lost their characteristic effects on the blood pressure and particularly on respiration. The lower graph shows a similar record made on a brown "Belgian hare" rabbit; here we noticed that the adrenalin effect is much less marked, as the blood pressure is raised from about 85 mm. only to 130 mm. whilst tyramine and pilocarpine have their characteristic effects both on the blood pressure and respiration.

It is therefore apparent that if one tested these rice bases on a light-coloured animal with a high

adrenalin content, the effects would not be at all characteristic, whilst typical effects would be seen in dark-coloured animals with a low adrenalin content. These effects were very puzzling to us in the earlier days of this research when we were groping to find our way out through this maze of difficulties. Now, however, we know that when an animal—usually a dark-coloured one—gives a poor adrenalin response, the action of the bases to be tested will be typical. McCarrison in 1924 did not realise this factor when he was endeavouring to explain why the birds in his different experiments gave a different percentage of infection.

THE ROLE OF THE VITAMINES.

The work that has already been done on this subject is too sound to neglect, and for us to consider only the poisonous bases found in diseased rice. On the other hand we rather suspect that we are dealing with a partial association; that beriberi is caused by these poisons in the rice, but that their action can be antagonised by the vitamins in various ways which we will discuss presently. The experimental work on the value of vitamins in beriberi has largely been done on birds, pigeons, fowls, etc., which have been fed on polished and unpolished rice. Megaw (1923) showed from the post-mortem lesions, that avian and human beriberi were not identical diseases, as in the former atrophy of the heart occurred and in the latter hypertrophy and dilatation. Another point against these bird experiments is the fact that the proper food for them is seed or grain unhusked with plenty of grit in order to allow the gizzard to thoroughly powder the grain and prepare it for the digestive juices further down the alimentary canal. Now a bird kept penned in a cage without any access to grit, and fed only on polished rice is unable to finely grind up the rice, and must suffer from the effects of this lack of mechanical digestive process. Further it is not necessary to give diseased rice, for ordinary healthy polished rice will cause avian beriberi. These facts will combine to point out that avian beriberi is a disease due to the formation of poisonous bases formed from the rice in the alimentary canal of these birds, due to the result of the imperfect grinding of the rice in the gizzard, and possibly to the altered bacterial flora as the result of this indigestion. We have heard that a French worker Marchoux, (1920) in Indo-China is working on these lines, and considers that beriberi is an intestinal infection and the poisons are formed in the intestine, which would be quite possible in avian beriberi.

We will now consider the rôle that the vitamins play in this disease. Sajous first hinted that one of the functions of the vitamins was to supply the precursors for the various endocrine secretions: this must be a pure surmise until the chemical composition of these antagonistic substances is known to us. We

extracted the water-soluble bases from rice bran and tested them pharmacologically; see Graph X. This experiment was performed on cats; in one the total water-soluble bases

an increase in the force and amplitude of the heart beat; and a tendency to a fall in the limb volume, results which are distinctly antagonistic to the poisons in the rice.

GRAPH IX.

Showing the relationship of colour to the intensity of action to certain bases.

were tested, and here there is marked bronchial relaxation, a rise of blood pressure with

In the second experiment, the bases were separated into the four amino-acid fractions,

and in the lysin fraction a very powerful base was found which acts on the bronchiole muscles and blood pressure, and in spite of the high rise in blood pressure the limb volume was not altered at all.

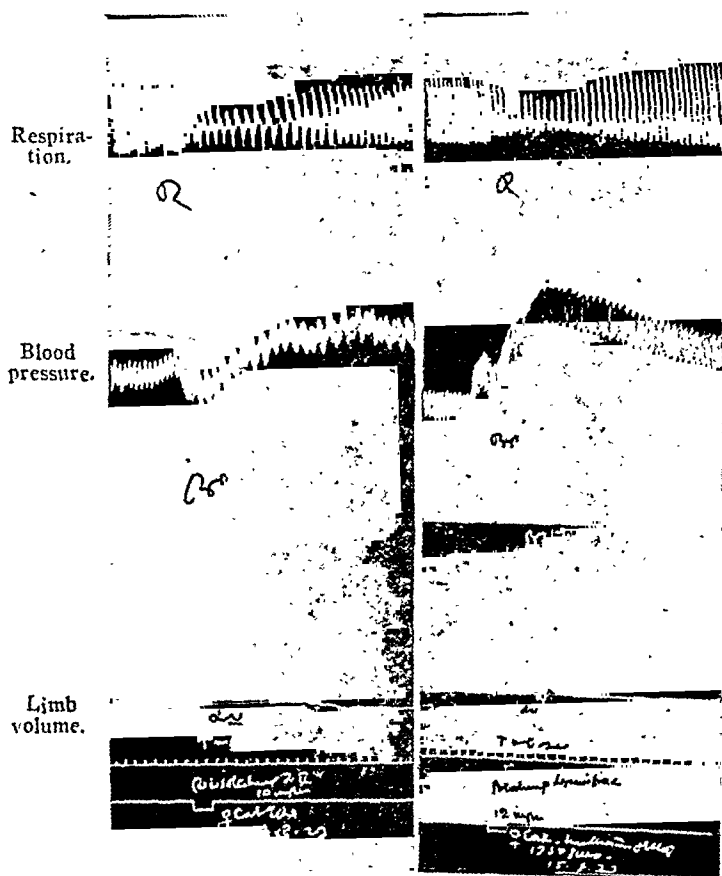

We therefore see that the pericarp of the rice acts in four different ways—

(i) Mechanically, by being impervious only to water and protecting the grain from invasion by extraneous bacteria and fungi.

(ii) The protective layer of bacteria. Professor Fowler of Bangalore has shown that in all seeds there is a layer of bacteria, specific for the particular plants concerned, situated in the space between the pericarp and aleu-

GRAPH X.

Showing the pharmacological effect of the bases obtained from rice polishings.

Total bases rice polishings. Lysin fraction rice polishings.

rone layer, and surrounding the whole grain. These bacteria prevent the ingress of extraneous bacteria that may possibly occur when the embryo ruptures the thinned out pericarpal layer over the embryonic site, during germination, and probably accounts for the increase in the vitamine content of germinating grain—compare hordenine in barley.

(iii) By virtue of these antagonistic water-soluble bases, anti-beriberi vitamins that are probably produced as the result of this bacterial action in healthy grain, especially if the

bacteria are rapidly multiplying during germination.

(iv) In birds the husks and pericarp are required for the mechanical grinding that occurs in the gizzard.

Whether these vitamins are the sources of supply of such essential endocrine secretions as adrenalin, thyroxin, etc., remains to be proved as yet. But there is little doubt that with starvation or malnutrition all these secretions are diminished, and with a liberal diet of fresh foods, these secretions are brought up to the normal limits of health. The essential factor for the production of beriberi or epidemic dropsy is the presence of toxins in diseased rice, the pericarp and its vitamins preventing these diseases either by preventing disease of the grain, or by virtue of the antagonistic substances present, or produced in the body.

FEEDING EXPERIMENTS ON MONKEYS.

The lack of animal accommodation that we suffer from at this School, and the difficulty of obtaining a sufficient quantity of the diseased rice prevented us from carrying out any large series of feeding experiments.

(a) Two monkeys were fed on boiled rice from a specimen of rice obtained from an epidemic dropsy case. The water was dried by cooking. Both monkeys developed diarrhoea in 8 days and showed signs of anæmia on the 15th day. Œdema of the feet commenced on the 19th day, and on the 29th day one monkey showed distinct puffiness of the face and œdema of the wrists and feet; the other only showed the œdema of the feet. The experiment had to cease on the 41st day, as the rice supply gave out. These two monkeys were given two bananas each day with their feeds in order to supply vitamins.

(b) Two monkeys were fed on the same rice as (a) but the rice was well washed after the rice water had been thrown away. Two bananas were given to each daily. These two monkeys only showed diarrhoea on the 11th day, which soon passed off. They remained healthy till the feeding was stopped on the 41st day.

(c) Two monkeys were given boiled new rice with two bananas; they remained healthy up to the 41st day.

This small experiment means very little by itself, but it confirms our view that most of the poisons concerned with the production of symptoms in epidemic dropsy diseased rice are water-soluble, and the disease could be avoided to a large extent by washing the rice well after throwing away the *kanji* water.

TREATMENT OF THE DISEASE.

The first point we have to consider under this heading is the means which we can take to prevent these two diseases.

(i) *The use of the water test in areas where these diseases occur.*—It is an extraordinary fact that most of the foodstuffs eaten by man are seen or selected by women, yet how few of them know the quality of the foods they buy for their households. With European women, if it was not for the fact that meat was stamped 1st or 2nd class, not one in ten would be able to judge for themselves the quality of the meat their cook brings each morning. The same applies to the rice, the staple article of diet in Bengal; we can now recognise diseased rice without the water test, but doubt whether we would ever have discovered it without first being shown the test by a rice merchant. (By this test we can more accurately judge the quality, the amount of disease, and the presence or absence of brushings. In this way people could avoid buying rice that is dangerous to health.) For legislative measures on this subject, one should have the additional safeguard of chemical, and pharmacological tests.

(ii) *Proper Preservation.*—The public demand a highly polished rice, as it looks nicer, whilst the miller prefers parboiling as it is easier to separate the husks, so that the common rice in most markets is a parboiled highly polished rice, i.e., a nice looking rice which is cheap. The grain has been preserved as the result of past experience by the following methods:—

(a) The cheapest grades are usually not protected at all, but sometimes a little chalk is added to increase the white colour, and more rarely rice bran is added as well. All these rices are parboiled and polished.

(b) The medium grades, were in former days usually steeped and hand husked, but are now largely parboiled and always machine milled.

To each 60 lbs. of rice one lb. of rice flour and 4 oz. of lime is added as a preservative. The lime keeps the rice dry and prevents the excessive hydrolysis of proteids and any further hydrolysis of sugars by yeasts into alcohol, etc., as both organisms require a good deal of moisture. Many fungi require a minimum amount of moisture and so the hydrolysis of starches into sugars is attained by the addition of lime. The coarser grained rices have the highest sugar content, so the Marwari selects the cheapest grade of rice and has it seasoned by lime to meet his requirements at a minimum cost.

(c) The best grades of rice are always sun-dried or steeped and generally hand husked, and selected from the finer long grain of the *chotan aman* crop. They may be preserved for a long time, 10 to 15 years, e.g., *baspathi* rice in the following way, from the attack of insects, weevils and moths, by protecting it in gunny bags and by the addition of *neem* leaves. From bacterial action the rice is pro-

tected by keeping it dry by the addition of lime, arrowroot or rice flour, and turmeric which is considered to be an antiseptic.

(iii) *Storage.*—In Calcutta the dangerous time for rice to be infected is between the months from July to the end of September. Infection may occur immediately after milling, when the rice is stacked in large pyramids on the ground before being put into bags. The lower layer starts sweating; when bacterial change takes place the temperature rises and the rice gets damaged. Under these conditions the rice merchants repolish the diseased rice and mix it up with healthy rice. If the rice is stored in gunny bags and kept in cool ventilated godowns no infections will occur, but otherwise the lower bags will commence to sweat and disease occur. A similar condition occurs in ships when the rice is stored near the engine room and over the bilge.

(iv) *In rices causing epidemic dropsy* the bases are largely soluble. A careful washing of this rice is required, especially in large messes and communities like jails, etc. The neurotoxin in beriberi rice is not water-soluble.

(v) *The necessity for vitamins in rice and in the diet.*—As long as the public demand a highly polished rice and do not object to parboiling, so long will the millers supply this rice. Steeping the rice and lessening the polishing processes would do much towards the prevention of the disease in the grain. The absolute necessity for the different food-accessories (vitamins) is apparent from all the work that has been done on the subject.

Curative treatment.—The first essential is to remove the source of the poisons; it is therefore not necessary to stop the eating of rice, but to see that the rice supplied is not in any way diseased. The next essential step is to increase the general vitamin content of the diet, as many of these people are poor and have been subsisting largely on a rice diet with very few additions; a short time in hospital with rest and liberal live diet makes all the difference to these poor people. Our other experiments on susceptibility have shown the importance of adrenalin in blocking the action of many of these bases. It is the most valuable therapeutic agent which we have in this condition, as it stops the action of these bases, and diminishes susceptibility. It is not a miraculous remedy restoring nerves that have been damaged or heart muscle that has been badly injured: the subsequent cure of both these lesions depends on the extent of irremedial damage. Graph XI illustrates the value of adrenalin in such a case where caffeine was first given, then digitalis, finally 2 minims of adrenalin intramuscularly twice daily: the urinary output suddenly rose, the oedema lessened and by the third day had disappeared. After a few days of

the adrenalin injections, suprarenalin gr. 1 and thyroid extract gr. $\frac{1}{4}$ was given between meals, twice a day for three weeks, in the hope of diminishing the susceptibility towards these bases.

We finally have to thank Capt. P. De, M.B., Assistant Professor of Pharmacology for his invaluable help during the course of these experiments which involved three years' continuous work.

CONCLUSIONS.

(i) Epidemic dropsy and beriberi are different clinical aspects of a toxic syndrome caused by the ingestion of poisonous bases formed in rice under certain conditions; although similar poisons can be formed in other foods under storage; e.g., tinned provisions, dried fish, etc.

(ii) This disease in the rice can readily be detected by the water test, and moreover these two

(viii) The bacteria and their spores, as well as their effects on the structure of the fruit, can be demonstrated by microscopical sections and cultural tests.

(ix) Experimentally by spraying rice or inoculating sterile rice media under certain conditions of temperature and humidity, the same poisonous bases are formed from the proteids.

(x) These bases pharmacologically produce all the signs of the disease; viz., oedema, heart effects, and para-sympathetic paralysis, and they are not present in the non-inoculated control rice media.

(xi) In sterile rice medium that has been inoculated by this bacillus under aerobic conditions at blood heat, the medium is liquefied and the water-soluble bases produced. The neurotoxin is only produced when the temperature is raised

GRAPH XI.

clinical entities are associated with two different grades of rice.

(iii) A spore-forming proteolytic bacillus of the *B. vulgatus* group is commonly found in such diseased grains.

(iv) These bacteria attack the fruit, particularly during the hot humid months of the monsoon, especially if the grain is stacked in non-ventilated rooms.

(v) Highly polished grain is more easily attacked owing to the loss of the aleurone layer and embryo, and the consequent exposure of the delicate cells of the fruit.

(vi) Parboiling kills the enzymes in the grain, and so further helps bacillary invasion.

(vii) Bacterial invasion of the rice occurs more commonly from the germ site, but in highly polished rice, it also occurs as commonly from the surface.

to 50°C. and the conditions made anaerobic by a layer of vaseline.

(xii) The difference in the relative proportions of the signs in epidemic dropsy and beriberi is due to these bacteria acting on two different grades of rice, and producing different amounts of the toxins causing neuritis and oedema.

(xiii) The poisons in the rice causing epidemic dropsy are water-soluble and are therefore found in the rice water, thus explaining the incidence amongst Hindoo widows, and in large communities; in the former the rice is cooked till dry, in the latter it is improperly washed.

(xiv) The neurotoxin found in rice causing beriberi is soluble in alcohol only, so that the disease is seen in persons cooking for themselves.

(xv) Individual susceptibility plays an important part when the amount of poison ingested

is small in amount, e.g., the small incidence sometimes seen in a jail population. When the quantity ingested is very large, e.g., in a whole family attacked by epidemic dropsy, it then determines the mortality.

(xvi) Hypo-adrenia in particular, and hypo-thyroidism to a lesser extent, increase the susceptibility towards these bases, and this in turn is closely correlated with colouration of animals.

(xvii) Rice polishings contain bases that are antagonistic to the bases found in diseased rice.

(xviii) The pericarp acts mechanically by preventing surface bacterial invasion of the grain, and is further aided by the protective layer of bacteria living under the pericarp of all fruit (Fowler).

(xix) Polished parboiled rice is the most dangerous of all rices and can be protected only by preservatives and proper storage.

(xx) Adrenalin in small doses, minimis ii intramuscularly twice a day, diminishes cell permeability and so relieves the cedema, and also antagonises the action of the water-soluble bases. To a lesser extent it protects the para-sympathetic.

STONE IN THE BLADDER.

By HENRY SMITH, C.I.E.,

LIEUT.-COLONEL, I.M.S., (retd.).

WITH reference to his article on this subject in the *Indian Medical Gazette* for April 1924, I should like to compliment Lieut.-Colonel A. J.

Vernon Betts, I.M.S., on his fine results,—results which are quite intelligible to an old hand in the game. His article suggests to me a few points of general interest.

Sounding for Stone.—You can detect a large stone with any instrument you pass. It is the small ones of a few grains weight which are of interest. I have frequently failed to sound them in a patient, anæsthetised and with the bladder distended, with a sound. The moment I passed a small lithotrite, however, and opened its jaws, the pebble dropped into its grasp. The late Colonel Keegan, I.M.S., made the same observation, but did not publish it. I would suggest that, when examining a child, when the result is negative to a sound, the operator should not be satisfied of the absence of stone until he has searched with a small lithotrite. I am confident that those who rely on the sound often send the child away until the stone grows bigger.

The same applies to sounding for fragments.

Irrigator versus Evacuator for the same purpose. I have frequently used an irrigator when my evacuator was out of order. It is satisfactory, but not as good as the evacuator. It can safely be used with four feet of pressure; I never used it with less.

Median lithotomy.—I would suggest that those proposing to adopt this incision should consider how little space there is between the rectum and the urethra. The space is so small that the rectum is opened more often than the published facts would indicate. I have thus opened it myself. Why median incision, when there is any amount of room laterally for either a Keith's operation or a lithotomy?

Suprapubic Cystotomy for Large Stones.—When the statistics extending over, say, ten years of the leading stone hospitals in India are classified, the results are very poor. I once did this, by sending a man round who got from the hospital registers details as to age, weight of stone, etc. It was found that perineal lithotomy gave a mortality of 10 per cent., whereas the suprapubic operation gave one of over 40 per cent. The litholapaxies done in all these hospitals gave a mortality of only about 2 per cent.; the two cutting operations being largely reserved for stones which could not be crushed. It was interesting to note that the suprapubic operation was done for just as small stones as was the perineal one.

In the perineal operation, the mortality was in direct proportion to the size of the stone. If the stone was small, the mortality was low; if large, it was high. To improve matters, I got Weiss to make a lithotrite about No. 24, to be used through a lateral lithotomy wound. This can be used to cause one or two fractures in a big stone, after which an ordinary No. 17 or 18 can be used to reduce it to fragments of such size as a medium sized forceps or scoop will extract. This in my experience is infinitely safer than

suprapubic lithotomy, and much safer than dragging out a large stone through a perineal wound.

The Art of Using a Lithotrite.—Language is a poor medium for teaching an art. I would suggest that beginners should get a fresh goat's bladder; distend it with air, and mould a plaster cast to fit it one-third up, and fix it to the mould with some first class glue. It could then be deflated, a nugget of medium hard brick put into it, a lithotrite passed, and the bladder again distended with water, the water being secured by tying a rubber tube around the neck tight enough to retain the water, but not so tight as to obstruct the movements of the lithotrite. A child's toy balloon would do as well, but is more or less transparent, so that one can see what one is doing, in place of relying on touch. By a little amusement of this kind, I think that one could acquire considerable dexterity.

Why is the suprapubic operation so fatal in India? Simply because we have not got sufficiently good nursing. It is due to extravasation of urine into the very loose cellular tissue around the bladder. For a day or two the patient appears to be all right. Then diarrhoea—septic diarrhoea—sets in, and the end is at hand. In India I am so opposed to leaving a suprapubic wound open that in prostatic enucleation or suprapubic cystotomy I consider that much better results would be obtained if the bladder wound were carefully stitched up, and a stab wound made in the breech and a small tube passed into the bladder to drain it through the breech for a few days until the bladder wound had healed,—than by leaving the bladder to drain through a suprapubic wound.

SERUM REACTIONS IN SYPHILIS.

By R. B. LLOYD, M.A., M.B., B.C.,

MAJOR, I.M.S.,

Imperial Serologist.

IN view of the increasing attention which is now being paid to the development of precipitation methods for the serum diagnosis of syphilis, the present time is opportune for a consideration of the relative value of the more important of these tests and a comparison with those which depend upon complement fixation, i.e., the Wassermann test.

It is a very remarkable fact that the test introduced eighteen years ago by Wassermann and his co-workers has held the field practically unchallenged until the last few years. This is in itself a great tribute. Modifications of the original technique have been numerous, the most important of which was the substitution long ago of extracts of normal organs for the extracts of syphilitic organs originally used as antigens; and in recent years many different techniques involving greater or less departures from the original test have been employed, as

standardisation of the technique has so far proved impracticable. The reaction broke entirely new ground, and the only criterion which could be applied to it was the degree of conformity with the clinical findings in an enormous number of cases all over the civilised world. This, of course, is the correct criterion, and it has further been amplified by careful post-mortem findings. That it has withstood this test is common knowledge; based on millions of cases it is known to be one of the most trustworthy of all clinical pathological diagnostic measures. It, however, depends upon the recognition of an unknown substance or substances in the serum—termed "reagin" by Neisser—and complicated reagents are required for its performance. The reagin is apparently produced by the tissues under the influence of the spirochaetes, and there are strong reasons for believing that it is not a defensive antibody; but that as Kolmer¹ states: "The complement fixation reaction is to be regarded as an index of the degree of infection rather than of immunity." Hence its use in the control of treatment. The Wassermann test was subjected to extremely stringent examination by a special committee of the Medical Research Council² in London, who in 1918 expressed the opinion "that there is no process of bio-chemical diagnosis that gives more trustworthy information or is liable to a smaller margin of error than the Wassermann test when it is performed with completeness and with proper skill and care." They further recommended that Wassermann tests should be concentrated in central laboratories, as a large turnover of work leads to increased efficiency.

The essential of the test is interaction between the syphilitic serum and the antigen, which latter is a colloidal suspension of lipoidal particles usually prepared from a normal heart. There is evidence that this interaction is the formation of a precipitate. Complement if added to the tube is fixed by this complex and is rendered incapable of effecting hæmolysis when sensitised cells are subsequently added, whereas if the patient be not suffering from syphilis hæmolysis occurs. The sensitised cells are, therefore, merely the indicator to show whether fixation of the complement has occurred or not.

If then the formation of a precipitate is the essential part it ought to be possible by changing the conditions of the experiment to render that precipitate visible, thus simplifying the technique and obviating the necessity for complement and the indicator reagent (sensitised cells). On these lines many attempts have been made to develop satisfactory precipitation tests, but in order to avoid too great complexity discussion will be limited to a few of the more important tests, the Meinicke³ reaction, the Sachs Georgi⁴ reaction, the

Sigma⁵ reaction of Dreyer and Ward and Kahn's⁶ reaction.

The obvious desiderata for a satisfactory test are:—

1. No unspecific reactions (false positives).
2. High degree of sensitiveness (avoidance of false negatives).
3. Simplicity of performance.
4. The results should, if possible, be capable of quantitative expression.

The earliest of these tests to be at all widely used was the Meinicke reaction (1917). There have been several modifications of this, and as his work cannot conveniently be condensed the reader is referred to the literature. Meinicke's latest method he terms the "Trübungsreaktion." After the Meinicke test came the Sachs Georgi reaction (1918). This in brief consists in adding diluted inactivated serum to the antigen suspension in salt solution and incubating. The mixture before incubation is opaque, and in a fully positive serum the opacity disappears and is replaced by a water clear solution in which is an abundant white flocculent precipitate. A considerable objection to the test is the long incubation necessary which involves the risk of bacterial contamination which may simulate a positive reaction. Opinions differ somewhat as to the value of the Sachs Georgi test. These different views are no doubt partly dependent upon slight differences of technique and also upon the varying sensitiveness of the different Wassermann systems with which comparison has been made; for as stated above the technique of the Wassermann test has not as yet been standardised.

Many workers find that, while agreeing in a high proportion of cases with the Wassermann results, the Sachs Georgi test is slightly less sensitive, particularly in cases under treatment. Further in the hands of some it has been found to yield a by no means negligible number of false positives as judged clinically; and while it has a certain usefulness if carried out along with other tests, reliance on this test *alone* is not advisable.

In connexion with sensitiveness it is not to be supposed, of course, that the extinction point of the serum reaction represents the end of the disease, for the evidence points in the opposite direction. *A fortiori*, so long as reagin is still present we must regard the disease as uncured. Further we must in treatment endeavour not only to reach the extinction point but to pass beyond it. As Harrison¹⁸ aptly puts it "Although the Wassermann test looks deeper into the patient's condition than the naked eye, it is not an absolute guide to a decision regarding the absence of syphilis." Conformably to this we should use that reaction which is the last to disappear, provided we are satisfied that no

false positives are yielded by the technique employed. The Sachs Georgi reaction being in the opinion of many somewhat deficient in sensitiveness in treated cases may fail here. It must be added that many of the leading workers do not agree that the Sachs Georgi test is deficient in sensitiveness. The sensitiveness is evidently rather variable. A large number of comparative observations by the Wassermann and Sachs Georgi reactions have been carried out in my laboratory and the results will be published shortly. I may say here, however, that while our results indicate that there is a general correspondence with the Wassermann results in a large proportion of cases, the test shews in our hands evidence of deficient sensitiveness.

In 1921 Dreyer and Ward introduced their well known Sigma reaction. This very brilliant piece of work is a precipitation test similar in principle to the Sachs Georgi test, though the technical details are different. This method was examined by a special committee of the Medical Research Council in 1923, who reported extremely favourably on it. Their results indicated that it is as sensitive as the Wassermann test in untreated cases; it seemed to be more sensitive in treated cases, and further the results are capable of quantitative expression. Dreyer lays special stress on this latter point. The measurement of the amount of "Wassermann substance" (reagin) present is no doubt important if it can be done accurately and without undue complexity. Vernes¹⁴ in Paris attempted the measurement of the amount of infection using for the purpose a special test. His method is complicated, but is in principle a modified Wassermann test, and it would appear to be doubtful if he achieved anything more than can be ascertained from the Wassermann reaction. The objection has been advanced against the Wassermann test that with fixed serum doses there must be some cases with more reagin present than suffices for a fully positive result, and that this excess will not be detected. Let us suppose there be twice the necessary amount present. We may call this 200 per cent., yet the result is the same as if 100 per cent. were present. It is contended that this is a source of weakness in treatment, for if the disease were so far improved that half the reagin had disappeared, there would still be enough left to yield a fully positive result. This might appear to suggest that the treatment had been ineffective when in reality the fact is otherwise. This criticism is undoubtedly justified. To what extent it is important practically the future will show. In the earlier stages of syphilis it is, of course, very much the exception for a positive Wassermann reaction to be uninfluenced by treatment, so that evidently the submaximal point is soon reached; and after that the diminution of the reaction shows fairly well how the case is going. The case is different with old lesions. The obstinacy of

the positive Wassermann reaction in this class of case is, of course, well known, and it may be of advantage to determine the Sigma values. In this connection it would be interesting to examine the Sigma values of the so-called "Wassermann-fast" cases to see whether treatment reduces the reagin "titre" or not. The reports of the British workers under the Medical Research Council¹⁵ were unquestionably very favourable to the Dreyer Ward test; this favourable opinion was not, however, borne out by the continental workers in connexion with the International Conference referred to below. Some of the workers appear to have found difficulty in obtaining results anything like as good as the earlier reports. Further, some authorities have expressed doubt as to whether the degree of flocculation present can be observed with sufficient precision to justify quantitative expression of the result. In the Dreyer Ward reaction the quantitative result is obtained by multiplying the factor representing the sensitiveness of the suspension used (suspension factor) by the dilution in which standard flocculation occurs, e.g., if a serum in a total dilution 1/50 causes standard flocculation, then 50×1.6 (suspension factor) = 80 units. They describe this result as 80 Sigma units. The test is somewhat laborious and meticulous attention has to be paid to the technical details, as it has been shown in a recent paper by Mörch¹⁶ (Professor Madsen's laboratory) that slight variations in some of the preliminary steps largely influence the final result. Dreyer himself also insisted on this. Harrison,¹⁷ whose experience is probably unrivalled, states "as to the reliability of the Sigma test there can be no doubt." Some explanation may, perhaps, be forthcoming of the weak results referred to above, and while a final judgment may be deferred for the present, it seems that this test has very considerable possibilities.

A conference of experts on serological standards in connection with the League of Nations Health Organisation¹⁸ assembled in Paris in November 1922, and presented among other questions reports on the sero-diagnosis of syphilis which may be summarised here. The conference did not report on the Kahn test, to be described later.

Professor Madsen (Copenhagen) reported that the Meinicke test is specific but insufficiently sensitive. The Sachs Georgi test is useful but gives a certain number of false positives as judged clinically, and has the drawback of not being quantitative. The Wassermann reaction is quite specific and gives a high percentage of positive results, its drawback being its complexity. The Sigma reaction is the most sensitive of all. It allows a quantitative titration but shows a certain number of false positives. He concludes that the Wassermann and Sigma

reactions are the best, but that both require to be carried out in adequately equipped laboratories by experienced workers. Wyler (London), working under the supervision of Harrison, finds a larger percentage of positive reactions with the flocculation tests with some slight tendency to non-specific reactions; and the latter in his latest book,³⁴ quotes the researches carried out by Wyler for the Medical Research Council which appear to indicate that in his hands the flocculation tests are rather more delicate than the Wassermann test and show few false positives. Experiments carried out at Warsaw by Milinska and Modrzejewska under the direction of L. Hirszfild showed that both the Sachs Georgi and Meinicke reactions are specific. He finds a remarkable concordance between the Wassermann and Sachs Georgi tests. In spite of their specificity he does not believe that either of these two flocculation methods can in their present state replace the Wassermann reaction. It is easier to make the flocculation test but there are difficulties in reading the results, particularly in slightly positive cases, and for this reason he considers the Wassermann test superior to the flocculation tests. Of the precipitation tests he prefers the Sachs Georgi. He expressed doubt as to the advantage of the quantitative results obtained by Dreyer's method owing to technical difficulties, and on the whole he is of opinion that these methods, on account of the difficulties in reading the results, cannot replace the Wassermann reaction. Moreover, he is not in favour of the calculation of the degree of positive reaction by units. On the other hand he thinks precipitation methods useful for comparing the sensitiveness of the Wassermann reaction in different laboratories.

Professor Kolle (Frankfort) states that considerable similarity exists between the results of the flocculation and the Wassermann tests. He considers that both the Meinicke and Sachs Georgi reactions should be performed side by side with the Wassermann test. He advocates the use of both the flocculation tests for the reason that in the Sachs Georgi reaction the antigen is cholesterinised, whereas in the Meinicke it is not. Muller (Vienna) concludes that the Wassermann reaction gives more often a positive result than the flocculation test: the greatest difference being found in latent syphilis, especially in cases under treatment, in tabes, sclerosis, and aortitis. Of the precipitation tests the most positive results were given by the Sigma reaction, with the Meinicke second and the Sachs Georgi third. Their investigations have shown that the best method known up to the present is the Wassermann reaction which gives when properly performed more valuable answers than the flocculation tests. With an equal specificity the Wassermann reaction will more often be positive, especially in cases of latent syphilis, and still more in cases of syphilis under treatment. He

further considers that the results of the Wassermann reaction could be brought to a higher degree of efficiency if researches were undertaken to arrive at an antigen of optimal efficiency. This point, which has been very carefully gone into in connexion with the flocculation tests, has not been sufficiently considered in the Wassermann reaction. In contrast to the results of Harrison and Wyler he finds all the flocculation tests inferior in delicacy to the Wassermann test in addition to the difficulty of reading the former. Of the flocculation tests in his hands the Dreyer has proved the best. It is as specific as the Wassermann reaction and it should be possible to simplify the technique. He will not dogmatise as to whether any one of the precipitation tests could be so far perfected as to reveal surely all those cases of syphilis that now the Wassermann reaction alone can detect, but he is tempted to say that the technique of the complement binding reaction constitutes the more delicate reagent, so that it can often reveal relations between serum and antigen that will never be accessible with any certainty to flocculation tests. At present we must certainly use the Wassermann test as well as the flocculation test.

Renaux (Brussels) is of opinion that the weak point of flocculation reactions consists in the difficulty of reading results. In the Sigma reaction, even if carried out with a standard flocculation, there is often doubt as to the degree of flocculation observed, and this affects the number of Sigma units attributed to a given serum. He considers that both the Meinicke and Sachs Georgi antigens have at times an unfortunate tendency to auto-flocculation, and in his opinion the observation of the Wassermann test is still the most accurate. The Sigma reaction is more difficult to read and requires more experience than the Meinicke and Sachs Georgi tests. Professor Sachs (Heidelberg) is of opinion that the Dreyer Ward reaction is giving increasingly good results from the point of view of delicacy, but there is some tendency to non-specific reactions. On the whole he is of opinion that flocculation tests show far-reaching parallelism both with the Wassermann test and with each other. It has not so far been possible to obtain complete concordance by the comparative testing of any two methods. There are some syphilitic sera which give a stronger result with the Wassermann test or with flocculation tests or only with one and not with another of the various flocculation tests. The divergences chiefly occur in cases of latent syphilis and syphilis under treatment. The various methods are, therefore, complementary to one another, and in that sense flocculation tests may at any rate be regarded as valuable auxiliaries to the Wassermann.

In view of the marked divergences brought out by the reports received, the conference decided

to compare the sensitiveness of the Wassermann tests in different institutions. They accordingly sent portions of the *same* sera to several laboratories of the first repute. Flocculation tests also were done on these sera. Considerable differences in results were obtained, the chief difference being in the quantitative titration of the Sigma test. In order to determine the cause of these divergences the Health Committee of the League of Nations decided to convene a conference at which the investigators were to make *simultaneous tests of the same sera* by the different methods. This conference was held at Copenhagen¹⁹ in November and December, 1923. 536 sera were thus simultaneously tested by nine workers, all of whom were experts. Full controls were included and elaborate precautions taken to ensure strictly comparable results. This is perhaps the most exact experiment of its kind yet performed.

After a long and thorough discussion on the results obtained, the following conclusions were unanimously approved by the conference. "The Wassermann test yielded in this conference the uniformly greatest number of positive reactions in known cases of syphilis. With regard to specificity, no unspecific results whatever were obtained by certain of the investigators, and on the whole results which were possibly unspecific occurred very rarely. The results obtained by those workers who employed several antigens were not better than those using one only. It is concluded that the preparation of the antigens and the determination of the precise dose of complement to be used are of at least as great importance as the use of multiple antigens. The best results were obtained with heart extracts. The work of the conference has shown that the flocculation tests cannot at present replace the Wassermann test. It must, however, be emphasised that, in the course of the present conference, they have yielded positive results in a certain number of cases of syphilis in which the Wassermann reaction was negative, although the latter test showed itself on the whole to be more sensitive.

It is, therefore, recommended that the Wassermann test and the flocculation tests be carried out side by side, since by such a combination the best results have been obtained. Comparing the various flocculation tests they found that the Meinicke reaction was specific but the results were on the weak side. As to the other flocculation tests the original reaction of Sachs Georgi has yielded, during this conference, more positive results in known cases of syphilis than the Sigma method, but conformably with this greater sensitiveness its specificity was found to be slightly impaired. Since, however, these findings do not agree with those which have been obtained in certain other laboratories, it is advisable to make further investigation in order to discover which of these two recommendable methods gives the better results.

The several methods for the serological diagnosis of syphilis should only be carried out in laboratories specially adapted to the purpose and by experienced workers."

It will be gathered from the above resumé of the result of the last International Conference that the Wassermann test is preferred to any precipitation test.

Kahn in America in 1922 published a test which seems likely to be generally used. His test is in principle similar to the Sachs Georgi test, but with a view of obviating the disadvantage of a long incubation, he varies the preparation of the reagents so as to use them in as concentrated a form as possible. To this end he uses undiluted serum and a specially prepared antigen. His method undoubtedly produces a highly potent antigen. Kahn's aim was to devise a test the results of which could be read quickly. He uses the antigen and serum in such quantities as produce the maximum precipitation. The result is so sensitive that it produces spontaneous precipitation in strongly Wassermann positive sera. There can be no doubt that Kahn's reaction is valuable and may go far, and it is now being exhaustively tested in many different laboratories. Considerable care is required in the mixing of the antigen to prevent non-specific precipitation. For satisfactory results the serum must be absolutely clear. Sera which contain fat or which are even slightly hæmolyzed yield unsatisfactory results.

The Kahn reaction is being very widely used in America, and is now attracting a good deal of attention in England, and its literature has already become extensive. A few of the reports may be referred to. Detweiler²⁰ in a comparative series of 1540 cases tested by the Wassermann and Kahn reactions found agreement in 94.2 per cent. Of the 90 discrepancies, 51 were Wassermann positive and Kahn negative. Out of these 51, 40 were proved cases of syphilis, most of them under treatment. The unproved cases were regarded as probably syphilitic because of the finding of persistent complement fixation in each case. The remaining 39 discrepancies were Kahn positive and Wassermann negative. Of these slightly less than half were proved cases of syphilis. The percentage of agreement in this series agrees closely with the figures given by Dreyer and Ward, Sachs Georgi and others. He makes the important point that the actual percentage of agreement is of little value unless the proportion of syphilitic cases in the series and specially the proportion of positive treated cases is stated, as very few discrepancies will occur in non-syphilitic sera; and if the series be chiefly made up of these the percentage of agreement is bound to be very high and may give rise to a false impression of the value of the test under examination. For

example Moody²¹ reports 98 per cent. agreement between the Wassermann and Kahn reactions in 1500 cases, but only 15 per cent. of these cases were syphilitic so that it does not give a true estimate. Detweiler concludes that while the Kahn reaction affords results remarkably parallel to the Wassermann test, it is not yet the equal of the latter in reliability. It fails principally in three classes of cases;—(a) treated syphilis, (b) early primary syphilis, and (c) cerebrospinal syphilis. Anderson and Fischer²² performed a parallel series of Wassermann and Kahn tests on 177 cerebrospinal fluids. They found agreement between the two tests in 68 per cent. only, and where they differed it was the Kahn that was weaker. They conclude that the Kahn test is useful but must be more worked out. Miss Rockstraw and Bent²³—to the former of whom I am greatly indebted for first showing me the Kahn reaction in America last year—have recently published a comparison of the Wassermann, Sachs Georgi, and Kahn tests in 1022 sera and spinal fluids. They found the Kahn test was more sensitive than the Sachs Georgi but slightly less sensitive than the Wassermann test with cholesterinised antigen. In the case of untreated syphilis there was close agreement (98.9 per cent.) between the Kahn and Wassermann reactions; but in the case of treated syphilis the agreement was less marked (86.5 per cent.). Comparison of the Sachs Georgi test with the Wassermann reaction showed that the former was often negative when the Wassermann reaction was strongly positive; and in cases in which a positive Sachs Georgi was obtained with a negative Wassermann there was generally no evidence clinically of syphilis. In the case of spinal fluids the Kahn test proved to be of little value.

The Kahn reaction is now being examined in this department. It is too early yet to give a definite opinion, but the results so far obtained are extremely promising.

While the above account is largely occupied with the advances made in the direction of precipitation tests, it must not be supposed that the Wassermann reaction has stood still. The chief advance recently has been Kolmer's²⁴ new technique which is believed to be very sensitive and valuable. Kolmer²⁵ has recently made the following estimate of the practical value of the precipitation reactions, "Summing up the subject it may be stated that the precipitation reactions are not as sensitive as the complement fixation reactions conducted with a technically correct and acceptable technique; that they are more subject to misinterpretation and should not be relied on alone for the serum diagnosis of syphilis. They may, however, be useful as controls in the complement fixation test, and for this purpose the Meinicke (third modification) and more especially the

Sachs Georgi and Kahn reactions are to be recommended."

SUMMARY.

It will be gathered from the foregoing that no finality has as yet been reached, and much fuller information will shortly be available. Meanwhile the present position may be summed up as follows:—

(1) While there are material differences amongst some of the leading workers regarding the value of the flocculation tests, there is a general consensus of opinion that the Wassermann reaction remains for the present the best test for the detection of syphilis, though one or more of the flocculation tests may be done in addition.

(2) The great advantage of the Wassermann test is its high degree of sensitiveness, combined with an almost total absence of false positives.

(3) While the earlier flocculation tests have not proved as satisfactory as was expected, the more recent developments are much more promising. Improvements in technique may very possibly enhance the value of the Sachs Georgi test. The Kahn test is simple and apparently very serviceable. The former of these tests is however not quantitative. The Dreyer Ward test is valuable and quantitative and the technique should admit of simplification.

(4) It is probable that some form of flocculation test will eventually attain to extended use; although the difficulty in reading intermediate grades of positive reaction is at present considerable.

(5) The occurrence of non-specific reactions in flocculation tests needs further examination.

(6) Before any particular flocculation reaction can be accepted as the standard test, it must be clearly shown to be capable of yielding satisfactory results with cerebrospinal fluid; since this is the direction in which syphilis therapy is concentrating.

A PRELIMINARY NOTE ON THE SUCCESSFUL TREATMENT OF KALA-AZAR WITH "STIBAMINE GLUCOSIDE."

By L. E. NAPIER, M.R.C.S., L.R.C.P.,

Kala-azar Research Worker (Indian Tea Association Endowment), Calcutta School of Tropical Medicine.

SEVERAL aromatic compounds of antimony have been used in the treatment of kala-azar and other diseases in which antimony is of value, and it does not seem altogether improbable that in the near future these compounds will altogether replace the antimony tartrates in the treatment of such diseases.

"Stibenyl" (acetyl-para-amino-phenyl stibiate of sodium) was the first of these compounds to be used with success, but our

experience in India with this compound in the treatment of kala-azar was very discouraging, (Napier 1923). Good results in the treatment of both "resistant" and previously untreated cases of kala-azar with "urea-stibamine" have also been reported (Shortt and Sen, 1923). About a year ago I published a preliminary note on the successful treatment of kala-azar with meta-chlor-para-acetyl-amino-phenyl stibiate of sodium (Von Heyden 471) and during the last few months, since we have been able to get a large supply of the compound, we have adopted this as the standard treatment for kala-azar in the wards of the Carmichael Hospital for Tropical Diseases in Calcutta.

A large number of aromatic compounds of antimony has been prepared up to the present, and it is probable that a much greater number will be prepared, so that therapy with these compounds can be said to be in its infancy, and it is more than probable that the best compound for the treatment of kala-azar has not yet been found.

Some of the essential qualities, namely, constancy of composition, stability and low relative toxicity, can be tested in the laboratory; but unfortunately there is no satisfactory method of testing the therapeutic properties of these compounds except by trial on patients. It is, therefore, essential that one should test continually the therapeutic qualities of new compounds which laboratory experience has indicated, whilst at the same time carrying out a thorough trial of the compounds which preliminary trial has suggested as the most promising. Thus, whilst using von Heyden 471 as the routine treatment in the wards, I have at the same time been testing the value of certain other compounds, mostly aromatic compounds, amongst them "stibamine glucoside."

STIBAMINE GLUCOSIDE.

Dr. Henry, of the Wellcome Chemical Research Laboratory, very kindly gave me a sample of this compound when I was in England last summer and has subsequently sent me a second sample. It is an aromatic compound allied to sodium para-amino-phenyl-stibiate with an antimony content of about 30 per cent. and a minimum lethal dose of about 500 mgm. per kilo.* The sample that I brought out with me, in sealed ampoules, was subjected to hot climatic conditions for two to three months, but there was little evidence that any change had taken place, although from our toxicity experiments here it seemed possible that there had been a slight

increase in the toxicity of the compound. This increase was not, however, a serious one, and still left the toxicity of stibamine glucoside as less than half that of any other antimony compound that we had tested.

TREATMENT OF THE CASES.

Altogether 10 cases were treated with stibamine glucoside. In August, 5 consecutively admitted cases were placed under treatment with this compound, and again immediately I received the second sample 5 more consecutively admitted cases were put under treatment, so that no selection of cases whatsoever was made. All the cases were proved to be suffering from kala-azar by the finding of the parasite either in the peripheral blood or in the spleen pulp, after spleen puncture. Eight of the cases had received no previous antimony treatment, and neither of the previously treated cases had had antimony injections within three months of applying to us for treatment. The compound, which is an easily soluble powder, was dissolved in distilled water to make a 4 per cent. solution and was injected intravenously in doses of 0.05 gramme to 0.3 gramme. An initial dose of 0.2 gramme caused vomiting in the cases in which it was given and abdominal discomfort was felt, if not actual vomiting, in the patients to whom I gave 0.3 gramme, so that as a routine measure in the last few cases I gave 0.1 gramme as the initial and 0.2 gramme as the maximum doses for patients weighing over 50 lbs., and it seems probable that this will be a good system of dosage to adopt. As in the case of most antimony compounds, children appear to tolerate relatively larger doses. The injections as a rule were given on alternate days.

The cure was confirmed by direct and cultural examination of the spleen puncture material in cases where the spleen was palpable, and of the liver puncture material where it was not, taken about one week after the last injection had been given.

The results of the treatment are given in tabular form and it will only be necessary to add a few additional details, that cannot well be tabulated, about each case.

Case No. 1—This case had been running a continuous remittent fever for some time before treatment was commenced, but the temperature was certainly showing a downward tendency, although it was over 100°F. on the day previous to the first injection. This patient was not emaciated, so showed little increase in weight after treatment.

Case No. 2—This was a weak, anæmic boy who had been running an irregular fever for some time. His temperature fell below normal after the first injection and only rose above normal towards the conclusion of his treatment when he had a typical attack of dengue.

Case No. 3—This was a boy who had had a course of 50 injections of sodium antimony tartrate, given by a private doctor, and had relapsed after a short period of freedom from fever. When he was admitted he was suffering from a high remittent type of fever; his

* Compared with 25 mgm. per kilo. for sodium antimony tartrate, 133 mgm. per kilo. for "Stibenyli" (Fargher & Gray, 1921), and about 160 mgm. per kilo. for "von Heyden 471"; the toxicity of "urea-stibamine" being about the same as that of "Stibenyli" (Brahmachari, 1922).

temperature did not rise above the 99.5° line after the first injection, but did not remain below normal until after the 8th injection.

Case No. 4.—This was a very bad case in which it was thought advisable to lengthen the intervals between the injections; he made a very good recovery, however, and after losing a few pounds of weight at the beginning of treatment registered a net gain of 11 lbs., but

at first but 48 hours after the fifth injection she collapsed quite suddenly and died within a few hours.

CONSIDERATION OF THE RESULTS.

As this is essentially a preliminary report a detailed comparison of the results here obtained with those obtained by the use of

Case number.	Race or Religion.	Sex.	Age.	Duration of illness prior to treatment in months.	Weight of patient on admission, in lbs.	Number of injections given.	Total amount of compound given, in grms.	Total relative amount in grammes per 100 lbs. weight of patient.	Duration of actual treatment in days.	Gain or loss of weight during stay in hospital.	Number of injections given prior to cessation of fever.	Duration of fever from commencement of treatment, in days.	Size of spleen below costal margin in inches.		Leucocyte count at end of treatment; number of corpuscles per cmm.	Evidence of cure.

* P=palpable but less than an inch.

† Subsequently slightly irregular.

refused to allow a spleen or liver puncture before discharge.

Case No. 5.—This was a very weak emaciated boy who was scarcely able to sit up in bed. I had to give him the injections with extreme caution as regards dosage and interval. His temperature fell to normal for two days after the 4th injection, but rising occasionally up to 100°, it remained irregular throughout the course of treatment, only remaining normal immediately after this was discontinued. He made a particularly good recovery, as during the first half of the course of treatment I expected him to die at any moment. He lost 7½ lbs. in weight during the first month of treatment but gained 13 lbs. before discharge.

Case No. 6.—This was apparently a very early case running a high continuous fever.

Case No. 7.—This case was running a high intermittent fever which persisted until after the fifth injection.

Case No. 8.—This child appeared to be very ill; he had a high continuous type of fever which only occasionally showed slight remissions. The first few injections made no impression on this fever, but after the fourth it began to show signs of coming down and it remained below normal after the 6th injection.

Case No. 9.—This was a European girl who, though she has been suffering from the disease for some time, did not seem to be very ill. She vomited after the early injections so that the dose had to be increased rather slowly.

Case No. 10.—This was an extremely emaciated Anglo-Indian woman, aged 28, who had been suffering from the disease for about 18 months during which time she had received irregular treatment. She was apparently in a dying condition when she was admitted, but she improved considerably during the first few days in hospital, so that I thought that cautiously administered treatment with this compound would give her as good a chance as anything. She appeared to improve

either "von Heyden 471" or "urea-stibamine" will not be attempted. It is, however, quite obvious that this compound is far superior in the treatment of kala-azar to the antimony tartrates and that it compares very favourably with either of the above-mentioned drugs. The average time of duration of treatment was about a month and could undoubtedly have been reduced, had any attempt been made to press the treatment. It is also quite possible that the treatment was continued for too long a period, but we have not found spleen puncture during the course of treatment a very reliable indication of cure and have found it more satisfactory to allow a short period to elapse after the last injection before carrying out spleen puncture.

My thanks are due to Dr. Henry, of the Wellcome Chemical Research Laboratory, for providing me with so generous a sample of this compound and for the details of its antimony content and relative toxicity before despatch.

ALCOHOL.

THE *Practitioner* of October 1924 is a special number devoted entirely to the important subject of alcohol as an article of diet and a medicine.

Such authorities as Sir Humphry Rolleston, Sir Arthur Newsholme, Professor Starling, Sir James Purvis-Stewart, Sir Leonard Rogers, Sir Frederick Mott, Sir Richard Douglas Powell, Sir William Whitla and Sir Thomas Horder contribute to the number.

There is a general agreement on the disadvantages of alcohol when taken in any but the smallest amount. By Professor Starling it is regarded as a sedative and depressant drug, it is admitted to have a certain food value, but is regarded as an unsuitable and inefficient food. It can aid digestion only by its action in increasing the appetite. In concentrated form it is an irritant to the gastric mucosa and in any considerable quantity it retards digestion. It does not appear to be a real stimulant to any of the organs of the body, but in disease it may possibly be of value as an easily absorbed food stuff and as a sedative.

It is dangerous to persons exposed to cold as it increases heat loss, and in large amounts lowers the sensitiveness of the heat regulating centres.

Sir James Purvis-Stewart emphasizes its action in blunting the inhibitory centres of the brain, so that the person who consumes it becomes less critical of his own actions. In larger doses it inhibits other centres of the brain and causes loss of control. Used for long periods it causes an insidious deterioration of brain and body which may escape notice until an accident or illness occurs, but which may lead to neuritis, polyneuritic psychosis, etc. Sir Frederick Mott deals with the influence of alcohol in causing insanity. It is usually only a contributory factor and not the essential cause. Mott has found from experience that though alcoholics in hospital practice often suffered from cirrhosis of the liver, those in lunatic asylums seldom did so; altogether the association between alcoholism and insanity is not nearly so close as between alcoholism and certain definite structural changes in the organs of the body. There is, however, plenty of evidence of a state of mental deterioration due to chronic

alcoholism; not to speak of cases of suicide and homicide for many of which alcohol is responsible.

Dipsomania is in itself a definite form of mental disorder but is not a certifiable form of insanity.

Sir Richard Douglas Powell discusses the relationship of alcohol to life insurance, and comes to the conclusion that there is little evidence that amounts like $1\frac{1}{2}$ oz. of whisky or a pint of beer taken daily with meals will cause any symptoms which are recognisable even by expert examination. When taken in excess of these amounts it is possible to obtain definite evidence of harmful effects. Even small quantities taken frequently, although they may never cause intoxication, seriously affect a person's prospect of longevity.

The usual symptoms of such a form of indulgence are chronic gastric catarrh, morning retching, etc., in the more definite cases, but coated tongue, tremor of the tongue and hands should arouse suspicion.

The person who drinks to excess, only once a week to the extent of becoming slightly intoxicated, may suffer no appreciable damage except from his liability to accident during the period of intoxication.

Dr. Stevenson quotes the interesting opinion of Pearl who found that persons taking alcohol in small amount at any one time during the day and never enough to become intoxicated live somewhat longer than abstainers, while those who occasionally take alcohol to the extent of intoxication have a markedly higher mortality than moderate drinkers and abstainers up to the age of 60. Moore finds that abstainers as a class live considerably longer than non-abstainers.

Dr. Stevenson suggests that in certain countries the total abstainer is often a "crank," and that cranks may for various reasons have a smaller expectation of life than other persons. It would not be safe, therefore, to assume that the use of alcohol in small quantities is helpful, it may be positively harmful even though it be admitted that in certain sets of figures the strictly moderate drinker appears to have the advantage.

The article by Sir Leonard Rogers on alcohol in the tropics is of special interest. He points out that Europeans in the tropics drink more alcohol than Europeans at home, partly from social reasons, partly from the mistaken belief that alcohol is necessary.

He emphasizes the fact that alcoholics are very bad risks when they suffer from fevers, dysentery, cholera, sprue, heat-stroke, etc. He adopts a cautious attitude towards the question of the effects of the moderate use of alcohol. He comes to the conclusion that as alcohol has been found to predispose strongly to heat-stroke, hepatitis and liver abscess,

there is strong evidence that its habitual use is very far from being harmless. He strongly condemns the use of alcohol in the treatment of dysentery, cholera and snake poisoning; he adds that he does not know of any serious tropical disease in which its regular use is of value.

Its claims to value in the prevention of malaria and other tropical diseases are not based on any evidence.

Sir Leonard's discussion of the use of alcohol as a help to the maintenance of health in the tropics is most interesting. He cites his own experience which is that he carried out 27 years of strenuous service without taking alcohol in any form. Those who know the quantity and the brilliance of the work performed will find it hard to believe that the addition of alcohol or any other drug to Sir Leonard's diet would have resulted in a greater or better output.

Sir Leonard is not a bigot on the subject of alcohol, he admits that he does not know of any definite evidence to show that very moderate amounts of well diluted alcohol if taken with evening meal after sunset will do any harm.

Dr. Francis Hare deals with the treatment of alcoholism and strongly advocates apomorphine in maniacal drunkenness, during the paroxysm of dipsomania, and for insomnia following on the reduction of morphia or other drugs. The dose varies from one-tenth of a grain to one fortieth of a grain hypodermically, the smaller doses being suitable when the hypnotic action is desired.

W. McAdam Eccles summarizes the evidence against alcohol in a most convincing manner on the following lines.

Alcohol is a drug with narcotic action even in small doses.

Alcohol is not necessary to the healthy human being, it is definitely injurious to the growing child.

It is likely to become a "drug of addiction."

The immoderate use of alcohol is fraught with danger, physical, mental and moral.

The total abstainer can never use alcohol in excess nor can he suffer any harm from the use of the drug. Any moderate user may become an addict.

Alcohol is not a necessity, its moderate use is a luxury which is not free from danger.

Alcohol is a fuel food, but is a bad and unsafe food.

Alcohol is not a direct cardiac stimulant nor is it a digestive, except in an indirect manner by promoting a sense of well being which will

increase the appetite and enhance the normal processes of digestion. The opponents of alcohol regard this action of alcohol in promoting a sense of well being as one of the greatest dangers of the drug and as conducing to the formation of "habit."

The action of alcohol on the central nervous system is to deaden first the higher control centres and then in succession the lower centres. There is no evidence that alcohol can possibly increase physical or mental efficiency in health.

Altogether the valuable series of articles in the *Practitioner* contain little in praise of alcohol but much in blame.

In strict moderation the use of alcohol is a small vice which does little harm, and which, under certain circumstances may even have good effects, but on the other hand, every one knows how easy is the transition from moderation to excess. Every one knows how hard it is for the average youth to endure the ridicule which is poured on the total abstainer. The normal healthy person would rarely drink to excess, but for the pernicious "treating" habit which leads to the consumption of three or four times as much alcohol as would be taken if everybody bought his own drinks.

In a well known R. A. M. C. mess in India treating was forbidden except on guest nights, and the consequent reduction in the use of alcohol was very great.

The promotion of good cheer of good fellowship and the loosening of the tongue of those who are retiring and shy must be placed to the credit of alcohol, so must its action in helping to "eliminate" those who are deficient in self control, but can these advantages be obtained without the terrible drawbacks attending on the use of alcohol? The advocates and the opponents of alcohol have one common ground, they regard the moderate use of alcohol as being better than its excessive use, so that there can be no two opinions as to the desirability of introducing such legislation as is calculated to diminish the consumption of alcohol. Scientists would probably agree that absolute prohibition of alcohol would be greatly to the benefit of any country, but they are not agreed as to the effectiveness of any of the methods of prohibition which have been tried.

The great experiment which is being carried out in the United States will be watched with intense interest; the balance of opinion at present is that it has been a great success on the whole, though it has led to serious abuses in certain cases.

A Note to Readers.

We hope to publish the review of the Indian Medical year, 1924, in our next issue. It has been postponed to the February issue in order, as far as possible, to cover the whole of the calendar year 1924.

A Mirror of Hospital Practice.

A CASE OF FRAMBÆSIA IN THE NICOBAR ISLANDS.

By F. A. BARKER, M.B., B.Ch. (Cantab.),

MAJOR, I.M.S.,

Senior Medical Officer, Port Blair.

I AM not aware that any case of yaws has ever been reported from the Andaman or Nicobar Islands, and therefore the accompanying photograph of a definite case occurring in a native of Nankauri, one of the Nicobar Islands, is of interest.

The patient reported sick in October, when the R. I. M. S. "Minto" visited Nankauri harbour. The disease had commenced about 7 months before, and the primary seat was clearly an abrasion on the left knee-cap which was still in evidence. The primary eruption caused a good deal of itching, and the distribution of the eruption as seen in October suggests that it was spread by scratching.

Smears from the granulomata showed *Spironema pertecquè* in abundance, and three injections, each of 0.5 grm. of Novarsenobillon have caused a rapid improvement in the patient's appearance.

The patient states that, though there is no other case in his village, the disease is very common in certain villages of Nankauri and the neighbouring islands. It has probably been imported by traders from Ceylon or the Malay Peninsula.

A CASE OF TYPHOID SEPTICÆMIA WITHOUT TYPHOID ULCERS.

By WILLIAM FLETCHER, M.D.,

and

J. E. LESSLAR,

Dipl. Med. Coll., Madras.

Institute for Medical Research, Kuala Lumpur,
Federated Malay States.

ONE of the earliest lessons which used to be taught to the student in the post-mortem room was the diagnosis of typhoid ulcers, and questions about their distinguishing features were frequently asked in examinations. The association in one's mind between typhoid fever and the typhoid ulcer is so close that it is almost impossible to think of the former without visualizing the latter; yet mild cases of typhoid infection without intestinal ulcers are probably not uncommon. Severe typhoid fever without lesions in the intestine is extremely rare, but several instances of this anomalous form of the disease have been brought to notice. Recently Zweig (1922) reported the fatal case of a woman in whom a pure culture of typhoid bacilli obtained from the blood and organs after death and a positive Widal reaction were the only evidence of typhoid infection. The remittent temperature suggested septicæmia. Although the disease at the time of death had lasted a fortnight, no specific changes were found in the small or large intestine. Rehberg (1921) recorded an instance of typhoid septicæmia in a soldier, which was characterised clinically by extremely severe septic symptoms. Bacteriological examination of the spleen showed the presence of typhoid bacilli, but contrary to expectation no evidence was found in the intestine to confirm the clinical and bacteriological diagnosis of typhoid fever.

The usual course of events in typhoid fever is probably as follows. During the incubation stage the organism pullulates in the intestine and gall-bladder, and while this is taking place, the patient passes typhoid bacilli in his stools and becomes what is termed a "precocious" or "incubation" carrier. This condition is followed in some cases, though by no means in all, by an invasion of the blood and an attack of typhoid fever. The organisms are carried by the blood stream all over the body, where they multiply and produce lesions in certain peculiarly vulnerable positions, among which are the collections of lymph follicles known as Peyer's patches. In rare cases there appears to be a local immunity of the intestine, or the invading bacillus has no predilection for the lymphoid tissue of the ileum, and the disease runs its course as a septicæmia unaccompanied by the usual intestinal lesions.

The case which we record here is remarkable, not only as an instance of typhoid fever without intestinal lesions, but also on account of its bacteriological complexity, due to the occurrence of both agglutinable and non-agglutinable strains of typhoid bacilli, associated with mannite-fermenting dysentery bacilli, in the same subject. The patient, an old Chinese labourer named Quan Thin, was admitted to the District Hospital at Kuala Lumpur on March 11, 1922, with a temperature of 103°. He stated that he had been ill for a month. There were no physical signs of disease except a few coarse râles over the lungs. For the first ten days after his admission his temperature ranged between 99° and 103°F. During the following week it was seldom more than 100°, and subsequently it did not rise above 99°. After the patient had been in the hospital for six days he began to pass dysenteric stools containing blood and mucus. Subsequently to this he became rapidly worse and he died on April 1, two weeks after his admission and about six weeks after he was first taken ill. The temperature chart and the general condition of the patient suggested an attack of typhoid fever in about the fourth week of its course, and on March 20 Mr. Vimvalingam, the Assistant Surgeon in charge, sent the blood to us for examination. It agglutinated an emulsion of *B. typhosus* in a dilution of 1 in 7000 and *B. typhosus* was cultivated from it on the same day. Specimens of the stools, which contained blood and mucus, were examined on March 22, 27, 28, and 29, by plating them on Holt, Harris and Teague's eosin-methylene-blue agar, with the result that dysentery bacilli of the Flexner group, belonging to Andrewes' type X, were found on each occasion.

When the patient died on April 1, twelve days after *B. typhosus* had been cultivated from his blood, widespread dysenteric lesions were discovered. There was an acute membranous catarrh involving the whole of the large intestine and the last six inches of the ileum. To our surprise we found no typhoid ulcers nor enlarged Peyer's patches. There were two scars, evidently not of recent origin, just above the ileo-cæcal valve. They were deeply pigmented; one of them measured 2 cm. and the other 3 cm. in diameter. The gall-bladder was very slightly thickened and *B. typhosus* was grown from it in pure culture.

The question arose, at once, whether the typhoid infection was of recent origin, or whether the patient was a carrier in whom a general septicæmic infection had arisen from a nidus of organisms in the gall-bladder, which might have been in existence for months or even for years. It is possible that Quan Thin was a chronic carrier of *B. typhosus*, and the scars in the ileum may have been

the signature of an attack of typhoid fever which occurred long before; he told the medical officer that he had been very ill with fever a year before his final illness. Perhaps malaria and dysentery had lowered his powers of resistance to a point where the typhoid bacilli were able to invade the blood stream and produce a fatal septicæmia. On the other hand, it is possible that the case was one of typhoid septicæmia from the beginning, and that there had been, at no time, any typhoid lesions of the intestine.

The results of the bacteriological examination of this patient were unusual and interesting. It is seldom that an Asiatic pauper dies from a single, uncomplicated disease, and Quan Thin was no exception to the rule, for he died from the combined effects of malaria, dysentery and typhoid septicæmia. Subtertian gametocytes were found in his blood shortly after he entered the hospital, and the following strains of enteric and dysentery organisms were found in his blood, excreta and gall-bladder.

Organisms cultivated from the blood. *B. typhosus* was cultivated from the blood on March 20, twelve days before the patient's death. This organism was agglutinated by his own serum diluted 1 to 1200. It was agglutinated by the Institute stock typhoid serum to almost the full titre, but it was not agglutinated by dysentery antisera. When this strain of *B. typhosus* was sown on an agar plate, the resulting colonies were found to be of two kinds. About 60 per cent. were rough and granular, with irregular edges; the remaining 20 per cent. were ordinary clear typhoid colonies with regular, entire margins, showing a double contour when examined by transmitted light. The action of both colonies on the usual carbohydrate media, and on litmus milk, was that of *B. typhosus*. No indol was formed by either of the strains in peptone water. The individual members of the granular colonies were longer than those in the clear colonies. When they were grown in peptone water, the majority of the organisms in both subcultures were found to be non-motile, and there were fewer active bacilli in those made from the granular form. The striking feature of the granular colonies was that they were not agglutinated by a typhoid serum. Immune sera were made by inoculating rabbits. The serum prepared with the granular cultures agglutinated the smooth culture and also the type strain of *B. typhosus* at 1:5000, but it entirely failed to agglutinate the homologous rough, granular strain. The serum prepared with the smooth culture also failed to agglutinate the rough strain, though it agglutinated the homologous smooth and the stock cultures at 1:6000. Absorption of these immune sera, with the non-agglutinable rough strain, removed the specific agglutinins

for the smooth strain and for the type *B. typhosus*. The rough, granular colonies were therefore a non-agglutinable variant of *B. typhosus*.

Organisms cultivated from the faeces. Cultures were made from the faeces on March 22, 27, 28 and 29, with the result that dysentery bacilli of the mannite-fermenting group were isolated on each occasion and, when the patient died, dysenteric lesions were found in the intestine from the ileum to the anus. The organism possessed the usual characters of Flexner's bacillus. Acid was produced by it in milk within twenty-four hours, and the reaction became alkaline on the fourth day. Indol was formed in peptone water on the seventh day. An immune serum prepared with the bacillus had a titre of 1:1600 for the homologous organisms and it agglutinated Andrews' X strain to full titre. It was agglutinated by the patient's own serum diluted to 1:60. A detailed examination of this organism was made because, until this had been done, we thought that we might be dealing with the same non-agglutinable typhoid bacillus which had been isolated from the blood.

Organisms cultivated from the bile. *B. typhosus* was grown in pure culture from bile taken from the gall-bladder after death. It was agglutinated to full titre by the stock typhoid immune serum and by the sera prepared with the agglutinable and with the non-agglutinable strains isolated from Quan Thin's blood during life. It was not agglutinated by the serum prepared with the dysentery organisms isolated from the faeces. An immune serum, made by inoculating a rabbit with the bacillus isolated from the gall-bladder, agglutinated the homologous organism, the stock *B. typhosus* and the smooth strain isolated from the blood at a titre of 1:6000.

SUMMARY.

Two strains of *B. typhosus*, the one smooth and agglutinable, the other rough and non-agglutinable, were isolated from the blood of an old Chinese labourer, whose serum agglutinated a stock emulsion of *B. typhosus* in high dilutions.

B. dysenteriae, Flexner, type X, was isolated from his faeces on each of four occasions when they were examined.

The patient died about six weeks after the commencement of his illness. There was no marked thickening or inflammation of the gall-bladder, but an agglutinable strain of *B. typhosus* was cultivated from it. There were two old pigmented scars just above the ileo-caecal valve, but there were no typhoid ulcers.

It is an open question whether the patient was a chronic carrier and the septicæmia the result of infection from an old focus in the gall-bladder, or whether, on the contrary, the gall-bladder had become recently infected as a result of the general septicæmia.

A CASE OF MUSCULAR DYSTROPHY, SCAPULO-HUMERAL TYPE.

By Dr. J. P. CULLEN, M.D. (Lond.), D.P.H.,

Chief Medical Officer, Burma Corporation Ltd.,
Namtun, N. S. States.

THE accompanying photographs illustrate a comparatively rare condition, muscular dystrophy of scapulo-humeral type. The front view shews the extreme limit to which the

Fig. 1.

arms could be raised, the wasting of the deltoids and lower parts of the pectorial muscles, and the bony prominences around the shoulder joints. The prominences above the clavicles represent the superior internal angles of the scapulæ.

The back view shews the characteristic winging of paralysis of the trapezius. The modern view of these myopathies appears to be that,—with the exception of the pseudo-hypertrophic variety, which is probably a distinct entity,—the various forms described under the headings "Erb," "Landouzy,"

"Dejerine," etc., types, shew no sharp differences, and that no doubt exists as to their fundamental unity.

The term "juvenile," often applied to these cases, is occasionally inapplicable. In the present instance the man is aged 30 years, and

Fig. 2.

first noticed the weakness 6 years ago. No family history could be obtained.

A USEFUL HYPODERMIC OUTFIT.

By Dr. J. W. TOMB, O.B.E., M.D., D.P.H.,
Chief Medical Officer, Mines Board of Health, Asansol.

THE universal use of hypodermic medication now-a-days necessitates the possession by the physician of an outfit which will secure the minimum waste of time in its employment with the maximum of surgical sterility. This is particularly desirable where the alleviation of pain or the control of uterine hæmorrhage is the object in view.

The hypodermic outfits sold by the large manufacturing houses are not only costly and tedious to assemble and sterilise, but require very considerable care in transport, particularly in rural or colonial practice, if breakage is to be avoided.

In the outfit described below it is claimed that cheapness, immediate and constant readi-

ness for use, practical sterility, portability and security from breakage have all been equally and effectively attained.

The outfit consists primarily of a three-piece 60-minim Burroughs, Wellcome & Co.'s all-glass hypodermic syringe, with a platino-iridium needle, size No. 27. These sizes have been selected on account of their general utility. The syringe when originally assembled is sterilised by boiling in its metal case and is never afterwards taken apart. The platino-iridium needle is also originally sterilised by boiling, but on all subsequent occasions is sterilised by heating in the flame immediately before and after use. As an additional security against contamination and to preserve the point against injury the needle is kept in an empty sterilised hypodermic "Tabloid" glass phial of suitable size with the point of the needle directed upwards and embedded in the cork, a pledget of sterilised cotton wool being placed at the bottom of the phial.

The "lamp" consists of an ordinary 2 oz. glass-stoppered narrow-necked bottle filled with methylated spirit and provided with a separate (locally made) brass or other "burner" with a wick of twisted cotton strands. When the lamp is required for use the bottle is unstopped and the burner, which sits loosely on the neck of the bottle, is inserted as in an ordinary spirit lamp. The spirit in the lamp is also utilised for disinfecting the skin of the patient at the site of injection, but where soap and water are at hand these may be used instead.

To wash out the syringe after use and at the same time to sterilise it and to maintain it constantly in sterilised condition and also to prevent the glass piston from sticking to the barrel, a mixture of equal parts of glycerine of carbolic acid and rectified spirit is provided in a $\frac{1}{2}$ oz. glass-stoppered bottle. The needle having been previously sterilised in the flame, five to six minims of this mixture are drawn into the barrel of the syringe on each occasion after use. The piston is then gradually withdrawn while holding the nozzle of the syringe upwards, so as to allow the mixture to escape and at the same time thoroughly to wash out and lubricate the whole barrel, the piston being subsequently replaced. A small tea-spoon is included in the outfit in which to dissolve the hypodermic tablets by boiling, and thus secure that none but sterilised solutions shall at any time be taken into the barrel of the syringe.

The tea-spoon may conveniently be omitted in town practice but will be found useful in rural practice in India. Water, however, need not be carried, as water of some sort is always available and is only used after boiling.

In the tropics it is often desirable to assist the cooling of the sterilised hypodermic solutions by immersing the tea-spoon to half its

depth in a little cold water in a saucer or other suitable vessel. Not more than 60 seconds are required for this operation, so that the delay is negligible.

The phials containing the hypodermic tablets are carried in a small cardboard box measuring $3\frac{1}{4}$ in. by $1\frac{1}{2}$ in. by $\frac{7}{8}$ in. which is packed with cotton wool at one end to prevent breakages. A second smaller "Vaporole" or similar cardboard box measuring $2\frac{1}{8}$ in. by $1\frac{5}{8}$ in. by $\frac{3}{4}$ in. also carried capable of holding three glass "Vaporole" capsules of hypodermic solutions such as pituitrin, ernutin, etc., for emergency use. To open these capsules a file from an ordinary "Vaporole" box is included.

1. Metal case containing syringe and needle.
2. Cardboard box containing tablet phials.
3. Cardboard box containing "Vaporole" capsules.
4. Bottle containing methylated spirit.
5. Bazar made burner with wick.
6. Tea spoon.
7. Bottle containing glycerine of carbolic acid and rectified spirit.
8. File.
9. View of syringe and needle in open metal case.

This whole outfit is contained in a stout cardboard box $7\frac{1}{2}$ in. long by 4 in. broad by $2\frac{1}{2}$ in. deep with a cover of the same material, which can easily be carried in the hand, bag, or great coat pocket the cover being secured on the box by an ordinary leather strap. The box is half filled with cotton wool to absorb shocks and to protect the contents from injury. As an additional protection against injury a layer of corrugated cardboard is also fitted around the inside of the box on all sides, a flap equal to the breadth of the box being left on one side which folds over the top of the contents underneath the cover.

For town practice the outfit, including the cardboard box, can be carried in a locally made leather case, or a stiff leather case thickly lined with felt and provided with suitable partitions might be substituted for the cardboard box.

A rough sketch showing details of the outfit is given above.

Corrigendum.—In our issue for last November, p. 571, in Dr. Huli Rao's notes on a case of imperforate anus, please read "there was no escape of faecal matter from the vagina" in the last sentence. We regret the oversight.—EDITOR, I.M.G.

Medical Research Workers' Conference at Calcutta.

We have received the following report of the recent conference of Indian medical research workers:—

From time to time articles have appeared describing the special medical researches now in progress in the various medical research institutions of India; and the need for further medical research has been emphasised on many occasions. Recently a very interesting and informal conference of the medical research workers throughout India has been held in the School of Tropical Medicine and Hygiene, Calcutta.

This conference, which was convened at the instance of the Department of Education, Health and Lands, Government of India, assembled on the 27th October and its deliberations lasted three days. The Director-General, Indian Medical Service, Major-General R. C. MacWatt, C.I.E., K.H.S., I.M.S., presided and the Public Health Commissioner with the Government of India, Lieutenant-Colonel J. D. Graham, C.I.E., I.M.S., acted as Secretary. Through the kindness of Lieutenant-Colonel J. W. D. Megaw, I.M.S., Director of the School of Tropical Medicine, Calcutta, the delegates attending had the advantage not only of a comfortable meeting place, but also of the environment and appliances of the School of Tropical Medicine, which all the visitors were able to examine at leisure. The delegates, 32 in number, who assembled were representative of all the provinces of British India, of the Army, and of the medical research laboratories.

Major-General MacWatt in his opening address, after alluding to the value of such gatherings in the interchange of ideas amongst workers, referred to the great loss to the Medical Research Department by the untimely death of the late Major F. W. Cragg, I.M.S., who succumbed to typhus fever whilst on the typhus enquiry. After reviewing the work which the Association was carrying on with its limited income during the year, he outlined generally the programme of work which had been proposed for 1925-26, giving a brief financial résumé of the present resources of the Indian Research Fund Association and showing how the present researches and those proposed were able to absorb the income during 1924-25 and the anticipated income during 1925-26. In addition to special grants to institutions, such as the School of Tropical Medicine at Calcutta where two Professorships are paid for by the Indian Research Fund Association and a grant is given in aid of leprosy research, and after providing for administrative and contingent charges, the income available was able to finance 13 researches and it was hoped would finance 15 during the coming year. Present researches include those of the Kala-azar Commission, leprosy in its various branches, bovine tuberculosis at Muktesar, helminthology at Manbhar, lapsing and typhus fevers in the N. Provinces, sprue, bilharziasis, anti-plague vaccine, anti-venene at Parel, Bombay, and indigenous drugs at the Calcutta School of Tropical Medicine.

It was pointed out that the crying needs of India in regard to extension of research work beyond the proposed programme could not be given effect to without further funds which were urgently required, and that a

programme of priority research such as that now awaiting attention would, when formulated, enable the Government of India to realise that the working spirit and necessity were there and that only money was lacking. The clamant need was for researches suitable for India, i.e., for such researches as dealt with the prevalent Indian diseases familiar to all, and the hope was expressed that owing to the quality and quantity of the teaching work now being done at the School of Tropical Medicine, Calcutta, the type of worker suitable for routine researches under expert direction would in time be available in numbers formerly unknown.

Further, the hope was expressed that as a result of the Conference, workers would return to their laboratories stimulated by contact with other research minds and that the time would not be far distant when part, if not all of the former grant-in-aid would be restored.

The proceedings of the Conference occupied the forenoons and afternoons of October 27th, 28th and 29th and during this period every opportunity was given to the delegates to explain the nature and progress of the several enquiries with which they happened to be connected, or which were proceeding within the areas they represented.

The enquiries proposed for the year 1925-26 were considered in detail, both from the research and from the financial points of view, and their merits were discussed with a view to framing suitable budget proposals for recommendation to the Scientific Advisory Board of the Indian Research Fund Association.

The researches which have been proposed for the next year include the continuance of the Kala-azar Commission and its ancillary enquiry in Calcutta, the continuance of leprosy research work under Dr. Muir and his assistants at the Calcutta School of Tropical Medicine, of the enquiry on lathyrism at Kasauli, of the three branches of the malaria enquiry, into Indian culicidæ, cinchona alkaloids and the administration of quinine, the continuance of the bovine tuberculosis enquiry at Muktesar, the continuance and enlargement of the scope of the helminthological enquiry in Bihar and Orissa, and of the research work on sprue, bilharziasis, anti-plague vaccine and anti-venene at the Bombay Bacteriological Laboratory and of that on indigenous drugs at the Calcutta School of Tropical Medicine.

As, however, it was recognised that this only touched the fringe of the research work necessary, even though it absorbed the whole of the present available income of the Research Fund, it was considered advisable to prepare a programme of priority research. This was done by a sub-committee whose findings were accepted by the Conference. Its report showed that at least five lakhs yearly should be spent on further research work on malaria, plague, cholera, dysentery, helminthiasis and on disease surveys and scientific examination and interpretation of vital statistics. The aspect of the application of the results of such research work to the prevention and treatment of disease was carefully considered by the Conference and valuable suggestions were embodied in its proceedings.

Briefly a very plain case was made out not only for the continuance but for the extension of medical research in India, and for its adequate financial support by the Central and Provincial Governments. It is hoped that by focussing the attention of the public on this matter of medical research in general and on the work immediately in progress in particular, further interest may be stimulated in the whole question, especially in its relation to the economic elevation of the Indian community.

Penta-trichomoniasis in Man.

A PAPER on this subject by Professor C. A. Kofoed and Dr. Olive Swezy in the January 1924 number of *The American Journal of Tropical Medicine* will be of considerable interest to laboratory workers in India.

On examination of over 25,000 stools from some 8,000 persons, *Trichomonas hominis* infection was found in 1.1 per cent. This figure is probably under the mark for the real incidence of the infection,—since the parasite tends to die out in the passed stool: and the authors claim that the best method of detecting light infections is to feed flagellate-free rats on such fæces,—a claim which appears at once to indicate their belief that infection may be acquired by swallowing the motile and vegetative phase of the parasite.

Dobell and O'Connor (1921) recognise three varieties of *Trichomonas hominis*, viz., *Tri-trichomonas* with 3, *Tetra-trichomonas* with 4, and *Penta-trichomonas* with 5 anterior flagella, but consider these to be only varieties and not different genera. The view taken by Kofoed and Swezy is that *Penta-trichomonas* is an entirely different parasite from the others. Structurally it shows six flagella, viz.:—(a) a group of four slender anterior flagella, arising at the anterior pole, passing forward, and beating in unison;—so much so that in the fresh state they may be mistaken for a single thick flagellum; (b) the prominent flagellum of the undulating membrane,—common to all varieties of *Trichomonas*; and (c) a sixth flagellum which arises from the anterior pole from the same basal granule as (b) and passes backward, free from and not attached to the body of the cell, along the margin opposite to that of the undulating membrane. This sixth flagellum has a rhythm entirely different from that of the anterior cluster of four. Further *Penta-trichomonas* freely ingests red blood corpuscles, whilst *Tri-* and *Tetra-trichomonas* do not; and there is evidence that it is pathogenic to man, whilst the other two are probably non-pathogenic.

Three cases are quoted of persistent and long-continued diarrhoea, where this organism was constantly encountered. One was an army officer who had had amœbiasis, but 19 consecutive examinations showed no amœbe. The second case was that of an army officer who also gave a history of amœbiasis previously, but 78 stool examinations failed to shew any amœbe. The third case was that of a school teacher resident for 18 years in the Hawaiian islands. There was no history of amœbiasis and no amœbe were found in 15 stool examinations. In all three cases the type of stool and the clinical condition were remarkably similar. The infection was resistant to treatment with emetine, bismuth emetine iodide and neosarsphenamine.

Trichomonas hominis is a very common intestinal parasite in India. At the Calcutta School of Tropical Medicine in the examination of 233 stools in 1922 from 185 patients, it was encountered 18 times. It is frequently present in the alkaline stools of the bacillary dysentery convalescent and has frequently been encountered in Calcutta with numerous ingested red blood corpuscles within it. It will be remembered that G. C. Chatterji in 1915 (*Ind. Med. Gaz.*, January, Vol. 50, pp. 1-9) described the prevalent type of *Trichomonas* in Calcutta as *Penta-trichomonas*, although he did not describe the independent rhythm of the independent sixth flagellum. He considered that it had a special association with dysentery and diarrhoea. Neither he, nor Kofoed and Swezy, however, appear to have excluded the possibility of the dysentery and diarrhoea as having been due to chronic Shiga or Flexner or other bacillary infections.

The authors note that *Penta-trichomonas* survives in rain and tap water for three days, and in normal saline for thirteen days. In common with *Tri-* and *Tetra-trichomonas hominis*, no cysts have been observed: and the authors suggest that infection may be acquired by swallowing the parasite in its motile phase. *Penta-trichomonas* can be cultured in 10 per cent. rabbit or human serum in Locke's solution at room and body temperatures.

The authors' suggestions as to the specificity and pathogenicity of *Penta-trichomonas* are interesting, but obviously further work and evidence are needed.

A Discussion on Post-Operative and Puerperal Mental Disorders.

At a joint meeting on January the 7th, 1924 of the sections of medicine, neurology, obstetrics, psychiatry and surgery of the Royal Society of Medicine in London, an interesting discussion on post-operative and puerperal mental disorders took place, and is recorded in the *Transactions of the Society* for April, 1924.

Dr. T. B. Hyslop, in opening the discussion, said that he did not think there would be much difference of opinion as to the importance of the role of heredity in the production of mental disorders occurring after surgical operations or in the puerperim. Mental factors of causation included anxiety, whilst in the case of puerperal disorder illegitimacy of the child was sometimes a determining factor. The influence of suggestion was also important; a woman who had had one attack of puerperal mania or melancholia should not be allowed to become pregnant again until the lapse of a sufficient number of years for her to have forgotten the previous experience. A curious fact was that a large proportion of those who suffered from puerperal insanity were brown-eyed. The acute febrile puerperal mania of septicæmic type which used to be seen fairly frequently in former days was now rare; (in India it is quite common). The types of puerperal insanity now commonly seen were (a) sub-maniacal; and (b) stuporose. Commonly they commenced during the night and seemed to be the outcome of the continuance of some dream-state. A most painful medico-legal question arose when a mother had killed her child during an attack of puerperal homicidal mania, and whose symptoms had subsequently cleared. She was adjudged "guilty, but insane" and ordered to Broadmore to await His Majesty's pleasure. He disagreed with the views expressed in the courts. A further point was the usual duration of puerperal mania and melancholia; he was accustomed to regard 6 weeks, 3 months, 5 months, etc., as fitting in with different types of the disease.

Sir Charters Symonds spoke from a personal experience in surgery of forty years. He could recall only four cases during that time where the mental disturbances resulted as a direct effect of operation, and all shewed different features. The first was one of mania in a patient aged 60, setting in after lumbar colotomy for malignant disease of the colon. The patient had had intestinal obstruction for a long time prior to operation; he recovered completely in six weeks' time, and died 18 months later from malignant disease,—the mental condition having been clear during the interval. Here intestinal toxæmia appeared to be an ætiological factor. The second case was a girl aged 20, suffering from suppurative appendicitis; the day after operation she developed mental disturbance, with singing and mild delusions,—the condition lasting 8 weeks. The third was an elderly, highly intellectual man, aged 76, also suffering from appendicitis, with frequent ejections of a brown fluid,—the patient himself inducing vomiting by applying the finger or a feather to the back of his throat. On the 8th day after operation he became excited with the mental balance upset, and refused all food. In three weeks' time he appeared to be in *extremis* owing to emaciation. A pint of saline was given subcutaneously into each axilla, and he passed a much better night. There was subsequently steady improvement and his mental disturbance gradually cleared. The condition was afebrile throughout. The condition did not appear to be one of simple senile dementia. The fourth case was a severe mental attack of mania in an excitable Jew, following on prostatectomy; yet—in his experience—prostatectomy in elderly men was often followed by improvement in the mental state, rather than the reverse.

At Guy's Hospital they saw every year cases of delirium tremens which came on after simple fractures of the tibia or fibula. The type of patient in this connection was usually a steady drinker, but one not accus-

ed to heavy alcoholic bouts. Their mental state remained normal until the accident occurred, whereupon delirium tremens set in. With regard to mental disturbance following pneumonia, the condition was usually transient, and removal to a mental home was not necessary. (The reviewer remembers the case of an elderly man convalescent from lobar pneumonia, who suddenly announced one morning when his breakfast was brought to him that he was the King of the Jews, and proceeded to throw his gruel at the nurse; he recovered with a fortnight's nursing.)

Dr. James S. Collier spoke from the experience of a surgeon with a large experience of cerebral surgery. In connection with tumours of the brain, mental reduction was common, but mental aberration was rare; even with lesions of the pre-frontal lobes, mental symptoms were for the most part completely absent. The very common and striking post-concussive insanity seems never to occur from operations upon the brain, even though the brain may have been severely handled during operation. Meyer's theory that such post-concussive insanity was due to traumatic oedema of the brain was probably wrong. He could recall only four cases in which operation upon the brain was followed by insanity. Three of them were almost identical; they were cases of tumour of considerable size situated in the central region of one hemisphere and the tumour was extirpated widely, part of the wall of the lateral ventricle being removed in the process. Shock was profound in all three cases, and mania of a violent type set in on the 3rd day, and persisted till death, which occurred within a fortnight. No family history of mental disturbance or other causative factor was present in any of the cases, nor was any obvious cause for death found at autopsy.

The fourth case was one of a large and long-standing tumour of the right occipito-temporal region; no attempt was made to remove it on account of its deep situation, but a decompression operation was done under hedonal anaesthesia. A week after operation the patient developed delusions and became suspicious, erotic and dirty,—finally becoming so troublesome that he was placed under certificate. Six months later he had recovered from all symptoms, and his mental state remained normal until his death some two years later from hæmorrhage into the growth.

Shock did not seem to be an ætiological element in these cases. In 1,985 cases of injury to the brain in warfare only 13 cases of insanity were noted, and in another series of 981 serious head injuries only 12 cases. Operations upon the brain were not in any way especially associated with the development of insanity, nor had he seen mental disturbance follow operations upon the pituitary, thyroid and adrenal glands. On the other hand he had seen three cases of melancholia follow removal of the prostate and also mental disorder following upon hepatic and renal operations associated with sepsis.

He did not think that anxiety and fear were potent ætiological factors; some of the afflicted patients were of the most stolid type. Nor did the severity of the operation appear to count, for it might follow upon the most trivial operation and yet not after severe cerebral operations. Nor did the nature of the anæsthetic appear to affect the issue. In fact post-operation mental disorder appeared to be as intangible a condition as non-hereditary insanity in general.

Mr. Aleck Bourne dealt with the ætiology and prognosis in puerperal insanity. He complained of the want of co-ordination in the study of this subject between gynaecologists and alienists. In all he had collected details of some 70 cases and had studied them, especially from the point of view of ætiology and prognosis. Pregnancy in the single state might count as a factor—36 per cent. of 61 cases observed fell into this group. Physical disease was an important ætiological factor;—the chief organic disease associated with the condition being puerperal sepsis, and here the mental disorder sets in with the febrile state and may last for months

after the fever has subsided. Eclampsia was the next most important ætiological factor; and occurred in 9 of the 61 cases analysed. The character of the labour,—whether straightforward or difficult—did not appear to influence the mental prognosis, except in so far as sepsis was concerned. Primiparæ formed a much larger proportion than did multiparæ of the cases, 59 per cent.; and 27 per cent. of the patients gave a family history of mental disorder, whilst 4 were themselves epileptic. Anxiety appeared to him an important factor; one patient was exceedingly anxious as to the outcome of her confinement as she was suffering from phthisis, and another's husband had been reported as missing during the war. A third patient gave a history of transient mental disorder at the onset of puberty.

Turning to the time and mode of onset of puerperal insanity, of 70 cases observed, 4 developed during the later months of pregnancy, 6 became affected during labour, 39 cases in the first week of the puerperium, 18 during the second week, and the other 3 cases up to six weeks after delivery. The manner of onset was very similar in the great majority; after some nights of sleeplessness and incoherent talk,—showing usually some condition of deep-seated anxiety, delusions developed, whilst the mother might take a severe aversion to her baby. On the second day there was restlessness with a tendency to exposure of the person and to attack the nurses; by the third day the patient was frankly maniacal. Some, however, became stuporose and depressed or morbidly religious with intervals of weeping and singing hymns.

As to end results, of 58 patients of whom details were known, 13 had died from the effects of the mental disorder. The condition of puerperal insanity was therefore a serious one; it might be accompanied by both suicidal and homicidal tendencies. Of another 35 cases, 28 had been discharged "cured" or relieved,—of whom an occasional case had relapsed, and 4 were still under observation in asylums. The cases due to uterine sepsis did worst; those due to eclampsia recovered—most of them within a few weeks. The average time to recovery of the different types of cases was from two weeks to three years,—the eclamptic cases recovering very rapidly, whilst those whose recovery was slowest were cases where the underlying ætiological factors were obscure. In all, 77 per cent. of the cases investigated recovered mental health. As to recurrence of puerperal insanity in subsequent pregnancies, there was clear evidence that an attack in one pregnancy was very liable to be followed by an attack in a subsequent pregnancy; but cases due to puerperal sepsis or eclampsia did not come under this category.

Sir Maurice Craig spoke of nervous symptoms rather than mental disorder following upon surgical operations. Here a certain proportion of patients broke down after operation because of the emotional condition following on anxiety. To secure sound and refreshing sleep after operation was exceedingly important; the patient who slept well after operation did not develop neuroses; alteration of blood pressure was also important; he had seen three patients who had developed delirious maniacal conditions within 24 hours of the removal of a large abdominal tumour. Immediate saline infusions might here have a good effect. Some patients indeed seemed to become mentally afflicted as soon as they had a collection of pus anywhere.

Mr. H. J. F. Simson said that in private practice puerperal insanity due to puerperal sepsis could be eliminated, and from the point of view of general practice, the important class of case was the one with a hereditary history. Should women with a clear history of mental disease in the family be allowed to become pregnant? It was a difficult problem upon which to advise. If an obstetrician were asked to empty the uterus of a mentally unstable woman at the fourth month of pregnancy on account of the development of mental disorder, he might as well state that he would do it by the abdominal route, and at the same time section and divide both Fallopian

tubes. He agreed with Sir Maurice Craig as to the importance of securing sleep in threatening cases. There were two occasions during labour when sleep was especially necessary; during the first stage when the mentally unstable woman suffered from shock more than did the normal one; and secondly, for at least 48 hours after the confinement. In the former instance hyoscine and morphia might be indicated, in the latter bromides.

Dr. Carswell drew attention to the greatly diminished incidence of puerperal insanity during recent years; was it due to diminished puerperal sepsis? Not entirely; because there was an increasing tendency towards medical care and supervision of the patient during her whole gestation. Dr. Cuthbert Lockyer commented on the grave importance of sepsis in the ætiology of puerperal insanity. At present many cases of puerperal insanity were sent to the asylums to be looked after by alienists; but they were still obstetrical cases and needed the attention of an obstetrician. It was well known that cases following upon eclampsia got well, but what of the cases following upon puerperal sepsis? There was need for the co-operation of obstetric physicians and psychiatrists in the country.

Mr. Albert Carless, speaking as a surgeon with thirty years experience, said that there would probably be fewer cases of post-operative insanity if surgeons were not in such a hurry to get their patients out of hospitals and nursing homes. He had recently had his own appendix removed, and was much hampered at being obliged to leave the nursing home 15 days after operation. The most vivid case of surgical insanity which he had seen during the war was one where it was proposed to perform gastro-enterostomy on a private case. The patient was so much upset by the prospect of abdominal operation that he tried to cut his throat the night before the operation, and the specialist concerned earned his fee,—not by doing gastro-enterostomy,—but by stitching up the wound in the neck. A surgeon should consider not merely the operation about to be performed, but also the mental state of the patient,—a point too often neglected. Further, if an obstetrician should be attached to the staff of every asylum, a mental specialist should also be attached to the staff of every lying-in hospital.

In concluding the discussion, Dr. Hyslop said that it had been varied and of great interest. It must be recognised that certain patients were in a condition of what might be termed saturated nervous instability before operation; the mere removal of a tooth might here determine the onset of mental disorder. On the other hand, once the patient was frankly insane, surgical operations might actually affect him beneficially. As to hyoscine, it enabled one to knock the patient over, but the subsequent difficulty of recovery was great. The co-operation between surgeons, obstetric surgeons and mental specialists was very necessary; but if a start was made with one specialist of an outside subject added to the staff of every obstetric or mental hospital, where was the process to end?

However he hoped that the discussion had had fruitful and interesting results.

League of Nations: The Prevalence of Epidemic Disease and Port Health Organisation and Procedure in the Far East.

Report presented to the Health Committee of the League of Nations by F. Norman White.

GENEVA 1923.

ARE wars necessary? A prominent economist in a book published in 1914 said that among the great nations wars were unthinkable and impossible. The events of August of that year quickly proved him untrue but the present financial and economical conditions of most of the belligerents support the truth of the arguments on which his conclusions were based. More and more humanity is becoming an organismal unit. Variations

in climates and soils, the distribution of minerals, the development of means of rapid communication and information are all tending to make humanity a collection of communities in which none is self-supporting but in which all are mutually interdependent. Greed, rapacity and envy will make differences and quarrels but these should not be allowed to disturb and disrupt the organism by wars. To bring this consummation nearer and to spread and propagate these ideas, the League of Nations was formed. With this side of the League medical men have more than a passing interest but it is with the more belligerent activities of the League that we are more concerned. War against parasitic disease is not a local affair but must be made universal and co-ordinated. The direction of this campaign is entrusted to the Health Committee of the League of Nations. Much work on epidemic disease has been already done on the continent of Europe but the present report represents the preliminary reconnaissance of a more ambitious campaign. The low forms of life whose parasitism on man produce the chief epidemic diseases, plague, cholera, and small-pox flourish in the hot moist climates of the tropics from whence these diseases spread by human intercourse, railways and shipping. The mission undertaken by Dr. Norman White to the Far East was to enquire mainly into the following questions:—

(1) The incidence of the more important epidemic diseases in the Far East ports and adjacent territories, their endemicity, the sources and modes of re-infection, and the means in force for their prevention.

(2) The part played by shipping in the spread of infection.

(3) The quarantine regulations in force and their results in practice.

(4) The possibilities of making information regarding the chief diseases more readily accessible, and devising a scheme for interchange of such information.

By the International Sanitary Convention of Paris an attempt had already been made to draw up a uniform code of rules regarding the measures to be taken in regard to the spread of disease by shipping. The nations signatory to this convention were nearly all European, however, and the regulations referred mainly to the prevention of infection reaching European ports with little regard to the preventive measures to be taken at the port of departure. It has been abundantly evident that the latter measures are by far the most important in the suppression of ship-borne disease. Dissatisfaction has been expressed therefore with these rules and their revision is contemplated. One main object of this Far East mission was to enquire into the feasibility of adequate enforcement of uniform and adequate rules at all ports of departure to reduce the risks of ship-borne epidemic disease to a minimum. With such rules in force, the necessity for elaborate regulations and procedure at ports of call would be greatly reduced.

The writer of the report visited most of the ports of the Far East and the report embodies the conditions he found and his conclusions. He has wisely avoided a very large report but has given a bird's-eye view of sanitary conditions in the ports and countries visited. His criticisms and suggestions are helpful and valuable. The report reveals the extent of endemic and epidemic disease throughout the Orient, and how much of this could be prevented by suitable and not by any means impossible measures, especially at ports of departure. Dr. Norman White's observations on plague are as might be expected very interesting and illuminating. The history of the plague since 1894 is an instance of the slow but sure carriage of disease by human intercourse, but he focusses attention on the fact that it is merchandise and particularly grain which is the carrier and not man himself. Measures designed for plague prevention and control, both municipal and international, have been largely directed against the human case and his contacts and have therefore not only been largely futile but have repelled the co-operation of the people

who suppress information regarding rat mortality, etc., for fear of sanitary reprisals. 75 per cent. of plague cases are one per house cases and isolation, destruction of clothes, disinfection of bedding and room, and segregation of the contacts—the usual municipal measures—are not only irksome but largely unnecessary and useless. Similarly a ship with a cargo of rice from a plague port is possibly much more dangerous than a ship with a case of human plague on board, but at present the latter is subjected to many regulations, the former being ignored.

The writer reviews the epidemiology of plague and its geographical distribution with regard to the variety of rat and rat fleas. *Xenopsylla* would seem to be the only genus of flea carrying plague to man, but many more observations and investigations are necessary to clear up the relative malignancy of *X. cheopis*, *astia* and *brasilensis*. In French Indo-China the musk-rat is stated to have been found infected with plague but these observations would seem to require repetition and confirmation. This rat has not been found infected in India. Absence of human plague is usually taken as indicating comparative absence of a rat epizootic, and anti-rat measures and observations and investigations of rat mortality in such places are neglected. There is great danger in such a course. The amount of human plague is not by any means necessarily an index of the rat plague epizootic. Where conditions favour a large rat population and especially where there is grain traffic, continuous observations of rat mortality should be carried out and anti-rat measures pushed instead of being abated even if there are no human cases. The revised international sanitary convention rules will be drafted on sounder lines than the old.

The constructive proposals put forward in the report include the formation of a sanitary convention for countries of the Far East, the signatories to which would agree to certain procedure in their own ports and lines of action in the case of shipping proceeding from and arriving at ports. Special stress is laid on the importance of preventive action at the port of departure instead of at the port of arrival. This is essentially sound. A distinction is drawn between "bubonic" and "pneumonic" plague as being two distinct diseases. Dr. White suggests that *B. pestis* in pneumonic plague is not the only causal factor but that symbiosis with some unknown organism is necessary. We are not aware of any experimental grounds for this statement which is based on the analogy of the part played by the pneumococcus in influenza epidemics. A sanitary convention, as proposed immediately supposed the establishment of a central epidemiological intelligence bureau, which the report suggests should be located at Singapore—precise information is the first essential for sanitary action. Telegraphic information of disease in signatory countries and ports would be sent to Singapore from whence such information would be telegraphed to signatory governments. The bureau would report annually to governments and to the League of Nations, and would become an important centre for the dissemination of epidemiological knowledge, for the standardisation of quarantine procedure and for the control of communicable diseases generally. A large part of the report describes the conditions during the last 5 years so far as communicable disease is concerned in Far East countries and the descriptions are of great interest. The writer's style is fluent, clear and pleasant to read. So far as India is concerned, the writer notes the improvement in recent years in regard to questions of port health procedure and equipment. There is need for well equipped quarantine stations at Indian ports and these will no doubt materialise when the revised international sanitary convention is agreed to.

There is much more matter of interest in the report which should be read by all interested in the co-ordination of sanitary effort. The great reduction of cholera throughout the East in 1920-22 is noteworthy; in many places it is ascribed to mass inoculation with cholera

vaccine—the absence of reaction makes this a much more feasible measure than in plague.

Small-pox is widespread in the Far East, but is perhaps not so prevalent as conditions of living and the constant presence of infection would lead one to suppose. Provision for primary vaccination is made in practically all countries and in the ports is fairly efficiently carried out. In Japan alone is re-vaccination compulsory, although in the Dutch East Indies many of the population are re-vaccinated. The most noteworthy small-pox epidemic of recent years occurred in the Philippines in 1918-19. Local administration had been lax in the preceding years and primary vaccination had been very imperfectly carried out. In 1919 fifty thousand fatal cases of small-pox occurred and nearly 90 per cent. of the cases investigated were children who had no marks of primary vaccination. The constancy of the seasonal prevalence of small-pox in the Far East is remarkable. Three-fourths of fatal cases occur in the first half of the year.

Indigenous Drugs.

In an article in the *China Medical Journal* of August 1924, B. F. Read, M.C., of the Peking Union Medical College deals in a most capable manner with the subject of Chinese indigenous drugs.

Apparently the problem in China is much the same as that in India and it is interesting to notice how it is being dealt with. Many standard drugs can be bought at a national drug fair which is held twice a year at Chichow in North China; the prices of such articles as rhubarb, orange peel, gentian and castor oil are much lower than those of the imported articles. In the case of these there is no reason for importing foreign drugs at all. The next class of drugs dealt with are substitutes, viz., drugs which can take the place of imported drugs whose actions are similar. The use of these substitutes will diminish bills of cost very greatly without any loss of efficiency.

The third group is a varied one, it consists partly of Chinese drugs whose composition is well known, but which have not received serious attention, partly of drugs which are well known in the West but which have been discarded because of their feeble action, and partly of drugs which need investigation. The order in which the scientific examination of these drugs takes place is:—

- I. Identification by a trained pharmacologist.
- II. Extraction and chemical analysis of essential principles.
- III. Physiological testing.
- IV. Clinical trial of drugs which are found to be of potential value.

The author realises the need for caution in work of the kind, he points out that undue optimism and exaggerated claims only serve to put back the clock of scientific progress.

It is interesting to notice that work in China is following on the same lines as have been adopted in the pharmacology department of the Calcutta School of Tropical Medicine. It is only by patient scientific work of the kind that indigenous medicines can be made available at cheap rates. There are doubtless many drugs in use by the practitioners of indigenous systems of medicine which have their value. That there are any drugs which will prove to be serious rivals of quinine, salvarsan and the like is extremely improbable, but even if research into indigenous drugs should not reveal any epoch-making remedies, it will at any rate provide us with definite knowledge as to the possibilities of obtaining active remedies at cheap rates in this country. It is quite useless to force people to use a drug merely because it is of indigenous origin. It must be as good as the imported drug and also as cheap, for if it is dearer the truly economical procedure is to sell to the foreigner something that we can produce more cheaply than he can and then to buy from him the drugs which he can produce more cheaply than we.

Nothing can do more harm to the economic development of a country than to insist on keeping its labourers employed on work which does not pay.

Tryparsamide in Neuro-syphilis.

LORENZ and others in the *American Journal of Medical Sciences*, of August 1924, report the results of the use of tryparsamide in 185 cases of syphilis of the nervous system. The drug combined with mercuric salicylate was effective in early cases of G. P. I. and meningo-vascular syphilis. In lobar cases it was less successful. Visual troubles occurred in 7 per cent. of all the cases treated and in 23 per cent. of the cases of tabes. These cleared up in nearly all cases after withdrawing the drug.

Treatment of Encephalitis Lethargica.

STERN, in the *Medizinische Klinik* of Berlin for July 27th, 1924, advocates the use of 50 to 80 c.c. of serum from convalescent patients given intramuscularly. Only 1 case out of 27 died and sequelæ were entirely prevented. The treatment unfortunately is only practicable when convalescent patients are available.

Treatment of Pruritus Ani, Vulvæ et Scroti

DR. M. P. MOORER of Asheville N. C. in the *Journal of the American Medical Association* of September 6th, 1924, describes a new method of dealing with these distressing complaints. He thoroughly infiltrates the skin and subcutaneous tissues over an area exceeding the surface affected, by 0.5 per cent. quinine and urea hydrochloride solution. Anesthesia is at once produced and the skin becomes smooth in a few days. Sometimes a second application is needed after one to several weeks and in a few cases a third treatment is required. After sterilization of the part, a small area is anesthetised by 1 per cent. procain and then the quinine and urea solution is used to infiltrate the tissues until the patient feels as if he were sitting on a cushion. It is advisable in most cases to give a preparatory dose of a quarter of a grain of morphia hypodermically to prevent after-depression. Not more than 10 c.c. of 1.0 per cent. solution of procain should be used, but up to 200 or 300 c.c. of the quinine and urea solution may be used.

Domestic Estimation of Urinary Sugar.

British Med. J., September 20, 1924, p. 504.

DR. F. C. EVE, Senior Physician, Royal Infirmary and Victoria Hospital for Children, Hull, describes a method whereby the diabetic patient can measure the daily variations in excretion of sugar. This is necessary for treatment by dieting; it is indispensable if insulin is employed.

The method, though rough and ready, has been found adequate and reliable.

METHOD.

Apparatus required.—(1) Urinometer, reading 1000 to 1040, in a packable form. (2) Yeast, fresh every few days, costing a penny. (3) Thermos flask (one pint). (4) An engineering students' book of squared paper. Every night at bedtime the patient washes out the thermos flask with very hot water, and then passes his urine into it. He adds a lump of yeast about the size of a hazel-nut, gives the mixture a good shake, and corks with cotton-wool. In a few hours, less than twelve, at blood heat, any sugar present will have been destroyed by the growing yeast, chiefly by oxidation into carbonic acid. The specific gravity of the urine after fermentation will be reduced to an extent proportional to the amount of sugar originally present.

Charting.—The squared copybook is graduated from 1000 to 1040 in its left-hand margin. Every half-inch of the upper margin represents a day, and is numbered with

the day of the month. Every night at bedtime the specific gravity of the warm, freshly passed urine (say 1040) is charted with a black dot; next morning the specific gravity of this same warm specimen is again measured, and perhaps has now decreased to 1018 owing to the destruction of the sugar. A red dot is placed at 1018 vertically below the black 1040 dot. Next day another pair of dots will be placed in the next vertical column, and thus two curves will be spun out which may be connected by a thin line, as in a temperature chart. The black curve will show the daily variations of the specific gravity of the urine; and the red curve will show the daily specific gravities after the contained sugar has been destroyed. The object is, by diet and insulin, to make the space between the two curves as small as possible. For obviously, if the urine never contains sugar, there will be no space between the two curves—that is, they will be superposed.

Reviews.

OPERATIVE SURGERY, COVERING THE OPERATIVE TECHNIQUE INVOLVED IN THE OPERATIONS OF GENERAL AND SPECIAL SURGERY.—By Warren Stone Bickham, M.D., F.A.C.S. In six octavo volumes, totalling about 5,400 pages with 6,875 illustrations. London and Philadelphia: W. B. Saunders Co., Ltd., Vol. I., pp. 850. Vol. II., pp. 877. Cloth, 50s. net per volume.

Books on operative surgery differ widely in their character according to the class of readers to which they are addressed. Those intended for students are usually unpretentious works, restricted mainly to the classical operations which figure so frequently in the examination room and so rarely in the operation theatre. Those intended for practitioners and young surgeons form a class of which there are several fine examples in the surgical literature of this country. They crystallise the author's experience of what is best to do and how to do it, the views of many surgeons are discussed and criticised, leading us to the author's own views and the description of his favourite technique, followed by briefer descriptions of alternative methods. Such books are usually the work of one man, whose individuality colours every page of the text; they make the personal appeal of the teacher and one turns to one's favourite book for counsel in difficult cases, as to a tried and trusted friend.

The work before us is of a totally different character. It is of colossal proportions, covering the whole field of surgery, including all the special branches; it is the work of a single writer and it deals with operative technique alone. There is no discussion whatever of the indications for operation, of the merits of different procedures or of the after-treatment and the results. Opinions may differ as to the utility of such a work, but criticism may not be based on this ground, since by his sub-title and in his preface, which he adjures us to read before we criticise, the author explains what he has set out to do and what he does not try to do. He tells us that he sets out to describe the common operations only, but he has gone much further than this, for there are few recognised procedures of modern times which will not be found in these pages. We confess to astonishment at the colossal industry which must have gone to the making of this book, together with admiration for the manner in which the author has maintained an even standard of treatment, which must have been very difficult when dealing with subjects in which he was not specially interested. We venture to guess that the surgery of the brain and spinal cord appeal to him more than the other branches dealt with in these two volumes, the treatment of this subject seeming to us to be on less stereotyped

lines, but we may have to withdraw this opinion when we have seen the other volumes on regional surgery.

Vol. I deals with general surgical technique, including anaesthesia, general and local, plastic surgery, amputations and excisions. The account of each operation is preceded by a systematic description of the surgical anatomy of the parts and surface landmarks. The descriptions of operative procedures in this volume are mostly on orthodox lines, but we commend to the reader the chapters on prostheses and on cineplastic amputations and their appropriate prostheses. The latter subject is one on which information is difficult to obtain at present, it is undoubtedly the method of the future for the upper limb, and the account here presented is both adequate and interesting. Osteoplastic and aperiosteal amputations are known in this country, they too offer a field well worthy of investigation. Apparently the author felt himself bound to describe all the recognised amputations, but we regret that he has seen fit to ignore the lessons of the war, which have rendered obsolete most of the amputations described, and that he has omitted all reference to the "seven-inch stump" amputation of the leg which has proved so useful. The modern light artificial legs of aluminium, being an American invention, should surely find mention in this book. Gillies' work on epithelial inlay grafts is a surprising omission from the otherwise excellent section on plastic surgery.

Vol. II includes operations upon the blood vessels, lymphatics, nerves, bones, muscles, tendons and joints (excluding excisions), together with the first two sections of regional surgery,—operations on the brain and spinal cord. It is almost hypercritical to refer to small omissions, but we find no reference to the use of pedicled muscle flaps in filling a bone cavity, or to the method of secondary nerve suture in two stages, the nerve being dissected out and the ends brought as near together as possible in the first stage, the process being completed at the second operation, a method vastly superior to such antiquated devices as turning down flaps of nerves, shown by war experience to be absolutely useless. Parham's bands of flexible steel have established their position in the operative treatment of fractures and should be mentioned. The anatomical sections in this volume are very repellent, long catalogues of structures in relation with each other, redeemed however, by the excellent illustrations. The sections on the brain and cord are unusually good. We were much struck with the value of a series of tables and diagrams; presenting the relations of the spinal segments and nerve roots to the bodies and spines of the vertebrae, another of the segmentary motor distribution, and a third showing the symptoms of cord lesions at all levels. These data will be found very useful by surgeons who have to operate on these difficult cases.

The book is one which will appeal mainly to specialists as a work of reference, but it is a great conception finely carried out, on which we congratulate the author very heartily. It remains only to add that the printing and paper leave nothing to be desired and that there is an abundance of excellent illustrations.

W. L. H.

THE DISEASES OF THE BREAST.—By Willmott H. Evans, M.D., F.R.C.S., Consulting Surgeon to the Royal Free Hospital. London: University of London Press Ltd., 1923. 495 pp. with 106 illustrations, of which 15 are in colour. Price 27/6 net.

So much work has appeared in recent years on carcinoma of the breast that a new monograph on the diseases of that organ is certainly needed. The present volume, though it incorporates all the newest work, suffers from a diffuseness of style which at times wearies the reader. However interested the author may be in congenital anomalies and in atrophy and hypertrophy of the breast, he is hardly justified in devoting nearly 30 pages and 14 full page illustrations to these subjects. On the other hand we find the very important subject of chronic

mastitis dealt with in 8 pages with only one illustration. Cysts of the breast are a constant source of difficulty in diagnosis, but these interesting conditions are all dealt with far too briefly. Nearly half the book is devoted to the subject of carcinoma and full justice is done to Handley's work on the method of spread of the growth and the indications furnished thereby for the very extensive operations now performed. The whole subject is dealt with in great detail, but it is surely unnecessary in a work of this character to give lists of the instruments required for excision of the breast, nor does one expect to find directions for sterilising instruments and ligatures. The remarks on the preliminary incision in chapter 35 might well include a description of the naked eye appearances of the various conditions likely to be met with in doubtful cases, since it is on these that the operator, especially if located in foreign parts, will in most cases have to make up his mind what he is going to do. Secondary operations, after the pathologist's report is received, are not popular in India and the examination of frozen sections cut during the operation has not as yet gained a footing in this country.

The illustrations, all full page drawings, many of them coloured, are a special feature of the book. They are culled from various sources, ancient and modern, and indicate the author's deep erudition in his subject. Many of them are reproduced from old books and illustrate conditions which are practically never seen in Europe nowadays. They will be of interest to surgeons in India, the land where the neglected tumour is only too often seen. The excellent anatomical figures in chapter I would be improved by the addition of reference lines and names to all the structures shown, and we consider that the operation of excision of the breast should be illustrated by a few figures. The author has evidently devoted a considerable amount of labour to the preparation of this monograph and we have pleasure in recommending it to practitioners.

W. L. H.

DIAGNOSIS AND TREATMENT OF ACUTE ABDOMINAL DISEASES, INCLUDING ABDOMINAL INJURIES AND THE COMPLICATIONS OF EXTERNAL HERNIA.—By Joseph D. Adams, M.B., M.S., F.R.C.S., pp. x and 558, with 46 figures. London: Baillière, Tindall & Cox, 1923. Price 16/- net.

TEN years have elapsed since the first edition of this book was published, but the surgery of abdominal emergencies has changed very little. In the former edition Dr. Cassidy collaborated with Mr. Adams and the book was somewhat of a novelty in that many conditions which are in the province of the physician, but which may nevertheless give rise to difficulty in diagnosis were considered, and instructive details of actual cases in which laparotomy was performed on a mistaken diagnosis were given. Although Dr. Cassidy has not assisted in the preparation of this edition, much of his contribution remains, so that the book is unaltered in character. Each section is complete in itself, which, though it leads to rather wearisome repetition in the accounts of symptoms and treatment, has yet the advantage of saving much cross-reference and enhances the value of the work to the practitioner.

The work is extremely practical, the symptoms and differential diagnosis of each condition are given with meticulous care and accuracy and with due regard to brevity. The treatment recommended is thoroughly sound and in accord with the views of the majority of British surgeons. We think, however, that in dealing with appendicitis with localised peritonitis (or appendicular perityphlitis as the author prefers to call it) the methods of Ochsner, which are steadily gaining ground in the United States, merit discussion. The chapter on intestinal obstruction is in our opinion the best and most complete in the book; it includes a useful table showing the frequency with which the various lesions were met

with in a series of 500 cases at St. Thomas's Hospital, ranging from 197 cases of intussusception to one case each of carcinoma of the small bowel and pressure from outside the bowel, and it is in this order that the individual lesions are considered, a most useful method for the young operator, leading him to look for the most likely things first. Mummery's method of "blind" cæcostomy in carcinoma of the colon is not discussed, which we think regrettable, as this method is much safer for an inexperienced operator than extensive exploration in patients who are in the grave condition to which such cases usually drift in this country before they are brought to hospital. Irrigation of liver abscesses by Roger's sheathed cannula is not now used in the treatment of amœbic abscesses, repeated aspiration and the administration of emetine being found to give perfectly satisfactory results.

The injection of calcium salts intravenously and intramuscularly as a precaution against hæmorrhage in operations on jaundiced patients might well be mentioned in the sections on operations on the biliary passages. Apart from these few criticisms, we consider this a good and useful book and we have no hesitation in recommending it to practitioners in this country as a sound guide in a difficult class of case. The paper, printing and binding are excellent and the price is moderate.

W. L. H.

THE SCIENCE AND ART OF ANAESTHESIA.—By Colonel William Webster, D.S.O., M.D., C.M. St. Louis: C. V. Mosby & Co., 1924. Price \$4.75. Pp. 214.

THE author's intention is to provide a small, concise manual on the subject of anaesthesia for the use of the general practitioner and medical student, and the book admirably fulfils the purpose for which it is intended.

The first chapter is devoted to a very interesting resumé of the history of anaesthesia. The physiology of anaesthesia is clearly dealt with, and in subsequent chapters the chief anæsthetic agents and their administration are described, that on ether, and its great advantages being particularly full.

The selection of the anæsthetic agent and its bearing on the nature of the operation and surgical shock is very instructive. In describing pre-operative and post-operative treatment the author rightly points out the fallacy of the time-honoured drastic purgation on the night preceding operation. The patient's viewpoint is sympathetically treated, and we venture to suggest should always be kept in mind by those who administer anaesthetics. This book is published by C. V. Mosby Company, in clear, large type and is of handy size. The book is very readable and although short, presents clearly the salient features of anaesthesia.

SPINAL ANALGESIA.—By F. R. Parakh, M.D., B.S., M.R.C.S., Honorary Consulting Surgeon, Parsi General Hospital, Surat, Chief Medical Officer, Parakh Hospital, Bombay. Bombay, 1923, pp. 92.

THIS little booklet opens in rather an unusual manner with a condensed table of the author's 229 cases operated upon under spinal anaesthesia, with 6 deaths, none directly attributable to the anaesthesia and only 3 cases in which there was failure to produce analgesia. The author then proceeds on the usual lines, detailing the history of the method, advantages and disadvantages, technique, indications and contraindications, etc. The author is temperate in his views and makes no exaggerated claims for the utility of the method, as do some of its continental advocates. In patients suffering from severe injury with shock, in urgent abdominal cases, in bladder and rectal surgery and above all in cases where, by reason of some general disease, the administration of a general anaesthetic is fraught with grave danger, it is the method of election.

The book is somewhat overloaded with quotations from authorities but for those who desire an introduction to a method which deserves to be more widely employed in India than it is at present, it should prove useful.

LOCAL ANAESTHESIA, ITS SCIENTIFIC BASIS AND PRACTICAL USE.—By Professor D. Heinrich Braun. Translated and Edited by Malcolm L. Harris, M.D., Professor of Surgery, Chicago Polyclinic. Second American edition from the sixth revised German edition. Pp. 411 with 231 illustrations in black and colours. London: Henry Kimpton, 1924. Price 25s. net.

WHEN the first English edition of this book appeared in 1914 the present reviewer had the pleasure of writing the notice of it for the *Indian Medical Gazette*. Local anaesthesia was at that time widely practised in Germany, but hardly used at all in England except for anaesthesia of mucous membranes. That such extensive operations as resection of a thyroid lobe or an exposure of the brain could be performed under local anaesthesia excited surprise amounting almost to incredulity, unaccompanied by any desire to imitate these feats. Times have changed, however, and "field block" and similar procedures are now widely advocated in America and even in England the field for this work is steadily increasing. Procedures which were surprising innovations when the first edition of this book was published are now commonplace and every surgeon must now know how to utilise the method in suitable cases.

The book has always been noteworthy for the "scientific basis" sections and in this new edition we find many chapters devoted to the experimental work by which the properties of the local anaesthetic agents were studied. On the practical side it has been brought well up to date, the newer methods such as parasacral conduction anaesthesia are well described and illustrated, and there is a systematic section in which all the main operations will be found arranged according to regions with directions for the appropriate form of anaesthesia for each.

A section on toxic effects following the injection of novocaine is useful, as one is apt to forget that even this relatively non-toxic agent may have dangers when in strong solution.

Many new illustrations have been added, but they are mostly reproductions of photographs and are inferior to the old blocks.

Braun's book was the first standard work in this field, its reputation is well maintained by this translation of the latest edition.

DISEASES OF THE NOSE, THROAT AND EAR FOR STUDENTS AND PRACTITIONERS.—Edited By A. Logan Turner, M.D., F.R.C.S.E. With 222 illustrations and 12 plates of which 8 are in colour. Pp. 413. Bristol: John Wright and Sons; London, Simpkin Marshall & Co., 1924. Price 20s.

THE late Major W. G. Porter's unpretentious work on Diseases of the Nose, Throat and Ear was a well known and popular work, addressed mainly to general practitioners, which was favourably noticed in these columns some years ago. The present volume dedicated to his memory, is the joint work of those engaged in the teaching and practice of the speciality in the Edinburgh Medical School. The book has been considerably expanded and has been rendered more useful to students by the introduction of an illustrated description of the clinical anatomy of the various regions.

Detailed accounts of most of the minor operations and of the more common major ones have been added and should prove useful to practitioners. Sections on bronchoscopy and oesophagoscopy are intended to furnish the reader with the indications for the use of these methods rather than to instruct him in the details of

those highly technical procedures. Throughout the book the main objective has never been lost sight of, to assist practitioners to deal scientifically with all the common affections and to recognise the rarer conditions which require reference to a specialist. The book is not written for the latter, and therefore theoretical and controversial questions are left on one side, the treatment of the subject being elementary except in the sections on the internal ear, where the complex nature of the subject has compelled some departure from this rule. The directions for treatment are clear and practical if a little didactic in places, the collection of formulae which was a feature of the old edition has now been expanded and forms a useful appendix. The book as a whole has been greatly improved by the additions, it is easy reading and meets the requirements of practitioners exactly: we have great pleasure in recommending it.

CLINICAL EXAMINATION OF THE EAR, NOSE AND THROAT.—By Bhagwan Das Uberoi, M.B., B.S. Published by R. L. Suri, The Students' Own Agency, Anarkali, Lahore. 136 pp. Price Re. 1-12.

THIS is a useful little handbook which should be very popular among students and Indian practitioners. The author is in charge of the Ear, Nose and Throat, outpatient department of the Mayo Hospital, Lahore, and he has here collected together his clinical lectures to students, together with the points of clinical importance in ear, nose and throat work. The book puts together in a brief and collected form easy and every day methods of examination, and the causes and diagnosis of the commoner diseases of the ear, nose and throat. The author makes no claim to originality in the book, but he has done his work well, and the student or general practitioner who cannot afford the more expensive type of book dealing with this branch of work, will find in this little book sound and straightforward instructions. The book is one of the best of this class of small handbooks for Indian students, published in India, that we have seen.

A SYSTEM OF RADIOGRAPHY: WITH AN ATLAS OF THE NORMAL. BY W. IRONSIDE BRUCE: 2ND EDITION.—Edited By J. Magnus Redding, F.R.C.S. (Eng.), L.R.C.P. London: H. K. Lewis & Co., Ltd., 1924. Pp. xii & 98. Price 30s. net. Illustrations 197.

THE original edition of this work was written with the intention of standardising radiographic technique and thus facilitating the comparison of normal with abnormal appearances in skiagrams.

It would be superfluous to dilate on the success of Dr. Bruce's endeavours in this direction, suffice it to say that no work on radiography has been more widely consulted.

Owing to the rapid advance of radiography and the general improvement in apparatus, a second edition was long overdue. But the possibility of its production was precluded by circumstances due to the great war and to Dr. Bruce's illness and untimely death.

The present edition is edited under the direction of Dr. J. Magnus Redding. The illustrations have been entirely renewed, while the general scheme and arrangement of the book remain unchanged. Radiograms taken from above or below the couch, with equal facility as regards standardisation, are produced. The general standard of the radiograms is excellent, though some of the more difficult subjects seem to have suffered in reproduction.

Skiagrams of subjects aged 10 years have been substituted for those of 15 years in the former edition. Developmental variations and abnormalities have been noted below each radiogram, a plan which deserves special commendation.

Owing to the plan of placing more than one illustration on each page, 88 additional figures have been added without increasing the size of the book.

The work is now thoroughly up to date and as a standard work of reference as well as a guide to the radiographer. It should be in the hands of every radiologist and surgeon.

J. A. S.

RADIOGRAPHY AND RADIO-THERAPEUTICS. PART I. RADIOGRAPHY.—By Robert Knox, M.D., Fourth Edition. Illustrated, London: A. & C. Black, Ltd., 1923. Price 40s. net. Pp. 448.

THIS book, which has been described as the standard work on radiology in the English language, has deservedly reached its fourth edition. It contains much new matter, particularly with reference to the radiography of the liver, gall-bladder and urinary tract, also fifteen additional plates.

It would be superfluous to dilate on the merits of this admirable treatise; suffice it to say that it contains within its covers a full and practical consideration of x-rays, radiography, radium and radio-therapeutics, and serves as a work of reference alike for the radiologist, physician and student.

The skiagrams with which it is illustrated are of the first order, so much so that one American authority describes it as a veritable atlas of roentgenology.

The author states in his preface to the present edition that in view of the more elaborate volumes dealing with the chest, and the gastro-intestinal tract which he has in preparation, it has been decided to leave these sections practically as in the previous edition. We hope that this defect will soon be remedied. As it stands, this work is regarded as the standard English work on radiography and radio-therapeutics, and it is a pity that any section should be inadequately dealt with.

We congratulate Dr. Knox on the further perfection of his great achievement.

J. A. S.

PRACTICAL CHEMICAL ANALYSIS OF BLOOD.—By Victor Caryl Myers, M.A., Ph.D. 2nd edition. St. Louis: C. V. Mosby Co., 1924. Pp. 232. Price \$4.50.

THE author is to be congratulated on the publication of this excellent volume containing the latest practical methods of bio-chemical analysis. It is encouraging to note that the study of micro-estimation of blood constituents which is of recent date only is making quite rapid progress, especially in America, where the book under review forms one of the standard works on the subject. The arrangement of the matter dealt with in the book is all that could be desired and in describing methods for practical analyses the author has given a wide choice.

We have no hesitation to say that the book is one of the most up to date works on the subject and we strongly recommend it to those who are interested in the practical study of bio-chemistry.

J. P. B.

THE LEUCOCYTE IN HEALTH AND DISEASE.—By C. J. Bond, C.M.F., F.R.C.S., pp. VIII + 84; Illustrations, 48 in 24 plates, 1924. London: H. K. Lewis and Co., Ltd. Price 12s. 6d. net.

THIS book is a record of the results of many years of close and intensive study of the biochemistry and physiology of the leucocytes of the body, chiefly of the polymorphonuclear leucocytes; and its author is to be congratulated on the unbiassed method in which he puts forward his conclusions, and also on the series of magnificent microphotographs incorporated in the volume. Here—incidentally—he makes use of a new method of studying the vital processes of the cell,—by viewing it under dark ground illumination.

The body is tremendously dependent upon its leucocytes for its protection against disease. Not long ago two

rival factions held the field; the one, the school of Metchnikoff, holding that the chief mechanism of immunity rested in the phagocytic activity of the leucocytes; the other, the school of Ehrlich, holding that the immunity principle depended largely upon the formation of antibodies in the plasma. The ordinary teaching in pathology to-day is that the truth is that immunity depends upon a combination of both factors, the cellulohumoral theory. And upon this basis has been built up an enormous, almost top-heavy, superstructure, with an almost incredible nomenclature of complement and amboceptor, of opsonins and aggressins, of end pieces and tail pieces, until to-day, the literature on immunity is almost too complex for the study of a single individual. And many investigators feel that we have lost sight of the wood among the trees: that what is wanted is a further collection of facts rather than the enunciation of further theories. And as a record of such a collection of facts and a fine example of the value of combining biochemical and microscopical methods, we would especially welcome Mr. Bond's book. It carries us into the realm of newly ascertained facts, but its author studiously refrains from speculations.

Briefly, we may try to sum up his findings as follows:

(1) The form and outline assumed by living leucocytes have very important bearings on their activities. Thus stimulated leucocytes—such as those emerging from a blood clot—in addition to forming the usual pseudopodial processes, protrude very fine and delicate fibrillar dendrites, by which they can adapt themselves to the finest surface irregularities of any substance or object with which they come in contact. (2) Secondly such stimulated leucocytes, also living pus cells, as any observer who has done much dark ground work will at once confirm, frequently shew an oscillatory movement of the cell granules, an indication of the chemical activity going on within the cell. (3) Further the lobes of the polymorphonuclear leucocyte frequently change in relative position to one another,—and a single lobe may travel along an extending fibre and become detached from the rest of the nucleus. (4) Thus in general the mechanism of phagocytosis is seen to be one of close physical adaptation to surfaces and of great chemical activity within the cell. (5) The liquor puris, like the blood serum, is inhibitory or poisonous to the living pus cells in proportion as it contains the products of cell disintegration or bacterial toxins. Washed pus cells, like emigrated leucocytes, can phagocytose foreign or toxic red cells without any previous preparation of such cells for digestion by the liquor puris. (6) In different diseases, the emigrating property of living pus cells varies very much; thus in malaria it is feeble, in acute pneumonia it is very marked. (7) The attitude of leucocytes towards their prey,—(such as the red corpuscles here used throughout for the experimental tests)—depends upon some reaction between the red cells and the serum, whereby additive toxic or opsonic substances are formed on the surface of the red cells by the serum. (8) In cyanosis from prolonged ether anaesthesia, for instance, the leucocytes shew an increased aggressiveness towards the red cells. (9) In the presence of insulin, the diffusion substance elaborated by the leucocytes is increased, and this may have an important bearing on the mechanism of carbohydrate metabolism by leucocytes. (10) The first stage in phagocytosis of red cells by leucocytes is that the latter secrete a substance, an erythro-leuco-agglutinin,—which secures mutual adhesion between the phagocyte and the red cell. This is followed by ingestion, and then digestion of the red cell. (11) A benzine-iodine test introduced by the author, shews that stimulated leucocytes secrete a "diffusion substance," which is not merely one of the ordinary oxydase ferments present in many living cells, but which appears to be related to the "idophilic substance" generally recognised to be present in living pus cells. This diffusion substance is exuded into the environment and prepares the prey for agglutination and ingestion. The same substance is also present in some normal epithelial cells, in some

cancer cells of epithelial origin, in the multinucleate giant cells of myelomata, and in certain marrow cells. (12) The erythro-opsonic capacity of a blood serum, under certain conditions is not removed, but is increased, by heating the serum to 56° to 60°C., the active principle is thus thermostable. (13) The evidence suggests that the erythro-opsonins and the erythro-toxins present in certain diseases are intimately associated; the former may, indeed, be derived from the latter. Finally, (14) substances can be extracted by an acetone process from the envelope of washed red cells, which, when again brought into solution, will sensitise red cells for ingestion by the leucocytes.

It will be seen that Mr. Bond's book is a most careful, lucid and interesting contribution to the literature. Teachers of pathology may possibly try to fit in his findings into the jig-saw puzzle of the present views and nomenclature with regard to immunity. We much prefer his own method of collecting new facts and leaving deductions to the future. The author's volume is one which is not easy reading, but which should be carefully studied by every thoughtful pathologist and research worker in the difficult subject of immunity.

R. K.

THE EXTRA PHARMACOPŒIA OF MARTINDALE AND WESTCOTT. Vol I, 18th edition. London: H. K. Lewis & Co., Ltd., 1924. Pp. xxxviii plus 1,163. Price 27s. 6d. net.

THE last edition of this remarkable book appeared in 1920. Since that date there have been many important advances in treatment nearly all of which are fully dealt with. The book is much more than an exhaustive compilation of all the most important recent work on drugs and their uses in treatment; throughout its pages there will be found the critical judgment of its expert authors on the methods which are advocated by a multitude of workers.

The great success of the book forms the best testimony to its value to the practitioner, every three or four years a large new edition is called for. It is quite impossible to review in any detail the contents of the 1,200 closely printed pages of the handy little volume. A very valuable feature of the book is that the newest and most fashionable drugs are discussed in a coldly critical manner, so that the doctor who forms his opinions from Martindale and Westcott is unlikely to be carried away by enthusiasm and afterwards to experience disillusionment. The cocaine substitutes, for example, are not vaunted as epoch-making advances, they are shown in their true light.

The over-praised emetine bismuth iodide is summarily dealt with as being too objectionable to patients for ordinary use: emetine periodide appears to be better in all respects, but most workers on tropical diseases are coming back to the moderate use of emetine which has the great advantage of doing all that is claimed for it, though it does not often succeed in sterilizing the chronic carrier of the entamoeba of dysentery.

The derivatives of chaulmoogra oil are impassionately discussed, the efficacy of those in common use appears to be undoubted, but one great boon which has resulted from the work of Rogers and others is that leprosy has been withdrawn from the list of diseases which were regarded as incurable. Exaggerated claims for the new treatment are to be deprecated, but an attitude of scepticism and pessimism will do even greater harm than undue enthusiasm.

In dealing with the derivatives of cinchona bark the authors bring the subject well up to date, the use of quinidine sulphate in auricular fibrillation is fully dealt with. Great stress is laid on the failure of quinine as a prophylactic in Macedonia during the war. From experience in India the reviewer would emphasize the importance of rejecting evidence as to the failure of quinine, unless the most rigorous precautions have been

taken to ensure the administration of the drug in the doses ordered and in absorbable form. Too many medical men regard the writing of a prescription as being the same thing as the actual taking of the drug. The experience of all workers who supervise their dispensaries is that when really administered quinine is one of the most trustworthy drugs in existence.

The account of the antimony preparations which have been used in kala-azar is rather disappointing, some of the most valuable drugs are not even mentioned.

The Extra Pharmacopœia is the daily companion and guide of thousands of medical men, no doctor who has had experience of the book would willingly dispense with its aid.

A MANUAL OF SURGERY (ROSE AND CARLESS).—

By A. Carless, C.B.E., M.B., M.S. (Lond.), F.R.C.S.; assisted by C. P. G. Wakeley, F.R.C.S. London: Baillière, Tindall & Cox. Eleventh edition, 1924. Demy 8vo. 1,600 pp.; 17 colour plates, 634 text illustrations, and a special X-ray supplement. Price 30s. net.

"ROSE AND CARLESS" has been the friend and counsellor of many generations of medical students and practitioners since its first appearance in 1898; its reputation is world-wide; in fact it may be said to be the leading standard text-book on surgery in the British schools. The new, eleventh edition is an advance even upon its previous excellence, and incorporates the experience gained during the war; indeed a special chapter on military surgery at the end of the volume will be found very useful by all military medical officers. In this edition the section on pathology has been revised by Dr. Cecil Bosanquet; that on diseases of the nose, ear and throat by Mr. C. W. M. Hope, F.R.C.S., surgeon to the Throat Department, King's College Hospital; and that on anaesthesia by Dr. Playfair, anaesthetist to the same hospital. The colour plates are literally perfect, and exceedingly instructive; that on strangulated hernia for instance will teach the student far more than any text.

For sound instructive teaching in surgery "Rose and Carless" is unrivalled and the volume is wonderful value for its price, both to the medical student and general practitioner. It is pleasant to be able to welcome a new edition, even better than its predecessors.

LEPROSY: DIAGNOSIS, TREATMENT AND PREVENTION.—By Dr. E. Muir, Research Worker under the Indian Research Fund Association, Calcutta School of Tropical Medicine. Cuttack: Orissa Mission Press, 1924. Pp. 29, illustrations 11, paper covers. Price 4 annas.

IN producing this little pamphlet, Dr. Muir has rendered a real service of value to the medical profession in India, since the lessons herein expounded are so important, the medical practitioner's knowledge of the disease usually so limited and inaccurate, and the price of the pamphlet so very cheap that it is within the reach of all patient and physician alike. The consecutive chapters deal with the importance of early diagnosis, methods of diagnosis—clinical and bacteriological,—subsidiary signs, differential diagnosis, predisposing causes, and the stages of the disease. Treatment is next considered, with a full description of the preparation and modes of use of the ethyl esters, counter-irritation, prognosis and useful rules for those under treatment. Finally comes a section on prevention, the factors determining transmission and precautions needed to be taken by the public, by lepers, and by their medical attendants. We may add that there are 11 good illustrations.

There is packed into this little brochure a wealth of expert and accumulated information which is nowhere else accessible. We trust that this pamphlet is but the prelude to a work of much larger proportions; in the

meantime we would particularly welcome it, and bring it to the notice of the general practitioner in India.

A MANUAL OF PLURIGLANDULAR THERAPY.—By H. R. Harrower, M.D. London: Endocrines, Ltd., 1924. Pp. 288.

THIS small brochure is published by Endocrines, Ltd., as a digest of previous publications, and covers the whole field of pluriglandular therapy. Whilst there is much in it which can hardly be considered to be as yet confirmed, yet the style is clear and readable, and the indications for such therapy under different conditions are well set out. The book will be found very useful by the general practitioner, not only as an introduction to the subject, but also for reference. We are asked to state that a few copies are available gratis from Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta, for distribution to applicants, on receipt of 8 annas to cover postage.

SMITH'S MEDICAL VISITING LIST FOR 1925.—London: Hazell, Watson & Viney, Ltd. Size $6\frac{1}{2} \times 3\frac{1}{2}$ ". Prices; in cloth for 25 to 100 patients, from 6s. to 10s.; leather with tuck-in flap, from 9s. to 12s.

THIS very attractive little book is exactly the thing for the general practitioner to have on his office table, and to carry with him on his rounds. It contains a miscellany of useful information, including medico-legal information and a prescriber's compendium. The actual visiting list itself contains ruled pages for keeping a record of visits, obstetric and vaccination engagements, patients' and nurses' addresses. Two excellent ideas are special pages for drugs and instruments wanted, and, for a list of things lent. The practitioner who buys this little book will certainly find it very useful to him in practice.

TREATMENT OF KALA-AZAR (IN BENGALI).—By Dr. Arun Kumar Mukherji, M.B. (Cal.). Published by S. C. Bhattacharyya, 23-B, Bethune Row, Calcutta. Price Re. 1-8.

THE first two chapters contain a brief account of the geographical distribution and history of the discovery of the parasite of kala-azar and in the following chapters symptoms, diagnosis, specific treatment and treatment of the complications of the disease are dealt with in a clear style. This little book will be a very useful guide in the treatment of kala-azar for many practitioners in Bengal and Assam.

THE FIRST LAWS OF HEALTH. A HEALTH READER FOR INDIAN SCHOOLS.—By Lt.-Col. J. W. D. Megaw, B.A., M.B., I.M.S., Director, Calcutta School of Tropical Medicine. With a foreword by Sir Leonard Rogers, K.C.I.E., F.R.S., F.R.C.P., Lt.-Col., I.M.S. (ret'd.). Humphrey Milford. Oxford University Press. London, Bombay, Calcutta, Madras, 1921. Pp. 91. Available in English, Urdu, Hindi and Singalese.

THE object of this excellent little manual is to set forth in clear and simple language the primary laws of Nature which are essential for healthy living and also the well established facts of sanitary science and ordinary diseases, a knowledge of which will aid all classes in preserving their bodily and mental health and in avoiding the common preventible infectious diseases which carry off so many lives in India. The names of the authors of the manual and of the foreword are a guarantee of the accuracy of the information imparted. As Sir Leonard Rogers states in his foreword, to impart such information successfully is no easy matter, but demands in addition to knowledge literary skill, and

an intimate acquaintance with the habits and customs of the people. Lieutenant-Colonel Megaw possesses these attainments and has used them with happy success in writing this primer for use in Indian schools. Not only children, but youths and grown up men and women, will benefit by the knowledge and advice imparted and we would wish to see a copy in every Indian household. The book is of a handy size, the printing excellent and the illustrations are numerous, apt and well reproduced.

A. D. S.

GUIDE TO THE INSTRUMENTS AND APPLIANCES REQUIRED FOR OPERATIONS AND THE DRESSING OF CASES.—By Lt.-Col. R. H. Castor, I.M.S. Second edition, 1924, revised by Lt.-Col. F. P. Connor, D.S.O., F.R.C.S. (Eng.), I.M.S. Paper covers; 34 pp. Calcutta: Messrs. Thacker, Spink & Co. Price Re. 1.

THIS little book will be found very useful by civil surgeons, hospital residents, and nurses. The author makes no claim to originality for the work, but it is just the sort of one for a busy civil surgeon to place in the hands of his assistant, or for a theatre sister. The chapters deal with rules for and the fitting up of the operation room, the names of instruments, anaesthetics, and lists of instruments which are required for different operations in ophthalmological, dental, aural, gynaecological and obstetric work, a useful glossary of surgical terms used for different operative procedures, and an index. The printing and general get-up of the book are distinctly good.

Annual Reports.

REPORT ON THE PRISON ADMINISTRATION OF BURMA, 1923. RANGOON; SUPERINTENDENT GOVT. PRINTING, BURMA, 1924. PRICE RS. 4.

WE regret very much to read in this report, which is by Lieutenant-Colonel H. H. G. Knapp, M.A., M.D., I.M.S., Inspector-General of Prisons, Burma, that it is the last which he will write, and to learn of his pending retirement, for Colonel Knapp's reports are not mere compilations of statistics, but human studies of the very difficult problems of prison life and penology in India. Thus, when he comes to sum up the immediate needs of the present day position, he advocates (a) a separate staff of matrons and wardresses for female prisoners; in fact, if possible, a separate female jail with a staff of women subordinates; (b) a special new jail for juvenile-adult prisoners up to the age of 21, to be run on "Borstal" lines; (c) the need for the improvement of the subordinate staff of warders, both in numbers and character; for, in spite of increased pay and concessions, deterioration rather than improvement is here recorded. The report of the Burma Retrenchment Committee acknowledges that the prisons in Burma are run on very economical lines, but, as matters at present stand in Burma (and India) jail life is no deterrent to the habitual criminal. "The present staff of the Moulmein Jail cost Rs. 24,349 in 1923 and I reckon that the proposed improved staff would cost about five times as much. Efficiency has to be paid for; you cannot buy a Rolls-Royce for the price of a Ford."

But in reality what is wrong in the Indian prison system is not merely the parsimony which adverse financial conditions impose upon it, but the uncertainty of punishment. "All the evidence goes to show that severity of punishments does not deter, but that certainty of punishment does. Years ago in England punishment was barbarous and uncertain, and crime was rife. To-day punishment is comparatively light, but

pretty certain." Further the Indian and Burmese public lack the education with regard to crime which is so marked a feature of the every day English citizen; in England a criminal is the enemy of the public, in India the public do not regard him as such. There is far too little control of children and young men by parental care and discipline. The criminal whose crime stands a very considerable chance of never being punished at all, tends to repeat it. Prison life, when once experienced, turns out not to be the torture which he had anticipated; in the absence of special provision, the first offender is housed together with the habitual and the recidivist, and by them taught crime as a systematic career. Finally, Colonel Knapp pleads for "the exploration of all known means whereby offenders can be dealt with otherwise than by incarceration," and holds up the American system of "probation" as worth following. A fact which should appeal to legislators in this connection is that in America the cost of the prisoner on probation is about one-twentieth of that of a prisoner in jail.

Every jail superintendent in India—and this includes most civil surgeons—knows of the reality and importance of the issues which Colonel Knapp here raises. But whether Indian legislators have ever even thought about them at all, we do not know.

Turning to the main body of the report, there were 7 central and 23 district jails open during the year, together with 4 subsidiary jails which are under the control of the Police Department. The central jail at Tharrawaddy, which is now in process of construction, is to house 1,500 prisoners, and the project for another at Pegu has been held in abeyance until it is seen whether the new accommodation at Tharrawaddy and elsewhere will be sufficient for all purposes or not. Examination of the Shan and other hillmen prisoners in the Myingyan Central Jail shews that these hillmen are unduly unhealthy and cannot stand the climate of the plains. "There ought to be a jail at Taunggyi or elsewhere for Shans and other hillmen, but I fear that this must wait till the Shans themselves decide to build one." The proposed leper jail near the two leper asylums at Rangoon has been abandoned, as the proposed site was found to be malarious. The proposal for building two jails near Rangoon, one for under-trial cases, short term convicts and civil debtors, and the other for long term prisoners has been abandoned. In its place improvements are to be made in the existing Rangoon Jail.

The daily average prisoner population for the year was 16,287 as against 16,607 in 1922. 81 per cent. of the prisoners are Buddhists, and the most meticulous care is taken to provide full religious facilities for all castes and creeds of prisoners. There was a satisfactory diminution in the number of juvenile prisoners admitted, 90 as against 124 in 1922, and it appears that magistrates in general are beginning to realise that to send a juvenile first offender to jail is to incur the risk of "creating rather than of curing crime." Literacy is extraordinarily high, 69 per cent. of prisoners being recorded as able to read and write, but Colonel Knapp considers that this figure is probably above the mark. The Burma Suppression of Brothels Act, 1921, accounted for the admission of an unusually large number of prostitutes to jail during the year. Habitual prisoners numbered 29.4 per cent. of the total number of 18,579 admissions during the year; and it is clear that some 30 per cent. of the jail population is present throughout most of the jails of India and Burma as an educational influence for evil upon the other 70 per cent. of those admitted for the first time. The two classes should, of course, be segregated from one another; were 30 per cent. of the jail population diphtheria carriers instead, probably the money for this reform would be found at once.

There was a slight all-round increase in the number of offences and punishments dealt out, as compared with the figures for 1922. Colonel Beit reported that at Moulmein the experimental issue of tobacco as a reward for good conduct had proved a failure; also the issue of

soap had to be stopped, as it was found that the soap was being used as a currency and for the hiding of forbidden articles. On the other hand, Major Flowerdew at Insein reports that the issue of tobacco after the day's work has materially improved discipline in the jail; it is allowed only to those who have been for three months clear of punishment.

Serious offences are relatively few. At Rangoon a warder reported a prisoner for loafing, and the latter threw a brick at him, causing fatal compression of the brain. At the same jail and at Bhamo there were isolated assaults on warders. The percentage of floggings is very low, only 0.23 per cent. of male convicts (women prisoners, of course, are never flogged); but it has now been ruled that the offences for which whipping may be administered shall be severely restricted, a state of affairs which will make prison administration more difficult still.

Insein and Myaungmya Central Jails are reserved for habitual prisoners. Here the rules of the game are well understood both by prisoners and warders, and the habitual prisoner is usually an exemplary one, in the hopes of earning remissions of sentence. It is hoped to soon make the jail at Thayetmyo also one for habitual prisoners only. One reform advocated by the Indian Jails Committee has been introduced during the year; convict night watchmen are now selected only from habitual prisoners, and do not include any of the casual class. This has resulted in improved discipline, and Capt. Smith, writing from Mandalay, dwells upon the value in Indian Jail administration of the convict warder. He is often a better warder than is the paid professional one, and the jails of India simply could not be carried on without placing such selected prisoners on warder duty.

Owing to representations made, the duration of time during which under-trial persons have been incarcerated pending decision of the case has been materially improved, a most welcome fact.

Financially the total expenditure of the year on the Department was Rs. 19,74,903, an increase of Rs. 88,502 on the figures for 1922. The increase is chiefly due to the entertainment of 142 additional warders during the year, the grant of house allowance to subordinate staff, and payments of increments earned by the jailor and warder staff as a whole. The jail dairies and gardens shewed a substantial profit, in addition to providing for the requirements of the jails themselves. Earnings by jail labour amounted to Rs. 2,38,167; the average earnings per prisoner being Rs. 17-15-10, and the average cost Rs. 106-10-0 per annum.

Turning to vital statistics, the dietaries were sufficient, and only 15 per cent. of prisoners lost weight after admission. Water supplies are being improved, and an electrolytic chlorine plant is being erected at the General Hospital, Rangoon, which may serve the jail and other local institutions also. During the year 118 prisoners were employed on microscopical examinations for hook-worm ova, of whom 28 were efficient. Lack of funds is interfering with the issue of two sets of clothing and of towels to all prisoners, but the best is being done with the funds available. The dry earth conservancy method is followed in most of the jails, but at Rangoon incinerators are used. The daily sick numbered only 24 per mille and deaths only 12.53 per mille. "No people get closer medical attendance than those who are the least meritorious of the community" writes Colonel Knapp, "and their healthiness bears witness to the efficacy of medicine, especially on its preventive side."

Cholera was practically absent,—one death only and in this the diagnosis was doubtful. Malaria chiefly affects Kyaukpau jail. A test at the special tuberculosis jail at Myingyan shewed only 16 per cent. of negative findings to von Pirquet's test. Sodium morrhuate was not altogether promising, but Colonel Jeudwine's method of intravenous injections of iodine in relatively large doses was tried, and the results warrant further test. The enteric fevers shewed a decrease, probably due to

universal vaccination against these diseases. A special campaign was conducted against hookworm disease, and all prisoners were examined and those found to be infected were treated, this accounting for 7,910 admissions to hospital as against 798 for the same complaint in 1922. Infection rates varied from over 80 per cent. at Rangoon and Insein to 10 per cent. and under at Shwebo, Magwe and other small jails.

The juvenile jail at Meiktila continues to do good work. Major Fielding at Rangoon writes with regret of the abolition of simple whipping as a punishment for lesser offences. Thus the Deputy Commissioner of Tharrawaddy says that he would like to punish youths guilty of such offences as travelling on the railway without tickets by simple whipping, but as the law stands, he is powerless to do so, and they are accordingly sent into the jail to mingle with habitual criminals. An English public schoolboy is often whipped for far more venial offences, indeed very few public schoolboys in England can have gone through their school days without some experiences or other of the kind, and the apparently more lenient sentence of imprisonment is fraught with far greater risks and dangers to the youth's future.

The number of visits by official visitors was only 255 as against 316 in 1922. Certain officers are singled out as having done excellent work during the year; especially Majors Tarapore, Fielding and Flowerdew and Captain Smith. Mr. Hitchcock of the Inspector-General's office staff retired during the year, after 35 years of most intelligent and valuable work.

REPORT ON THE JAIL ADMINISTRATION OF
ASSAM FOR THE YEAR 1923, BY COLONEL
C. H. BENSLEY, I.M.S., INSPECTOR-GEN-
ERAL OF PRISONS, ASSAM. SHILLONG:
ASSAM SECRETARIAT PRINTING OFFICE.
PRICE, RE. 1.

It is curious how alike are many annual reports by Inspectors-General of Prisons in different provinces of India. Their difficulties are similar; the want of funds for very urgently needed improvements is common to all; and the very difficult problems of the control of crime in India appeal to all of them alike and from an entirely different point of view from that of the courts. If we compare the report for Burma for 1923 with that for Assam for the same year, the general sections of either are very similar.

Thus Colonel Bensley complains of the mixing of the young first offender with the habitual criminal; such a procedure does not prove a deterrent to crime; rather it creates the criminal in place of reforming him. "It is taking upon one's shoulders an enormous responsibility to send one of these youths to jail where the very air which he will breathe is contaminated with the germs of evil. I consider that there can be little or no excuse for sending such an offender to jail for short periods. What we require is a special institution of our own for dealing with those cases which sentencing courts find it impossible to deal with otherwise than by imprisonment."

Secondly, comes the evil of short term sentences. "It is satisfactory to note that there has been a decline in the number of sentences not exceeding three months; but all the same as many as 584 persons received sentences not exceeding one month and 1,029 sentences exceeding one month but not exceeding three. The passing of these short sentences is very undesirable; they are not deterrent, nor can they be made reformatory even under the best of jail conditions. We do not want to familiarise these first offenders with the inside of our jails. I fear that the importance of separating habituals from casuals has been overlooked in this province. I do not think that there has ever been realised the amount of evil contamination the habitual prisoner is capable of, and first offenders, guilty of only

petty crimes, should be kept out of our jails by all means possible, and when it is necessary to send a first offender to jail, it should be for such a length of sentence as will be deterrent in nature and which will enable us to do something towards reforming him whilst he is in jail. Our jails are simply turning out criminals, and this, I am convinced, is mainly due to the fact that so little attention has been paid to the separation of habituals and casuals in our jails. I have been able to effect some improvements. But, limited as they are by financial stringency and based on faulty jail construction, they cannot pretend in any way to perfection. However, something has been done."

Then follows a short and most instructive essay on the objects of imprisonment, and what we should aim at during the offender's imprisonment in the way of discipline and reformation of character. Even the Indian criminal, if caught young, is amenable and susceptible to moral influence; his mentality is still almost childish; but "evil communications corrupt good manners" and too often jail is an educational influence for evil. Special jails for youthful offenders, run upon the Borstal system, are badly wanted in India; but—as usual—there are no funds available, and an Indian Howard is still to seek. Also the probation and ticket-of-leave system, and advisory committees of non-officials to help ticket-of-leave men and prisoners on probation to get work, are badly wanted. Here there are unbounded opportunities for philanthropic bodies, but as it is, there is a good deal of lukewarmness even about official and non-official visitors to jails. The Discharged Prisoners' Aid Societies are very helpful, but they simply do not exist in Assam. Legislative assemblies are incessantly enquiring about prison administration; the questions asked are legion; but who of the many enquirers has ever studied the very difficult problems of penology with special reference to Indian conditions? America is trying to deal with the youthful offender by a system of liberty on probation; Great Britain has its ticket-of-leave system for habitual offenders; but in India we send both first offenders and hardened habitual criminals to jail together for short or long periods, therein to mingle, so that evil may corrupt what is still impressionable and still not essentially evil in character.

With regard to all possible measures of segregation, the jails of Assam are hopeless. There were 13 escapes from jail during the year. 9 from outside and 4 from inside the jails, and all of them due to negligence. "Nearly all our jails are insecure owing to defects in construction; many of them are surrounded with bamboo palisades only, and in the case of those with brick walls, the walls are too low. There is no use suggesting remedies when funds are not to be had; the strength of the warder guard is far too low," and morale has in general deteriorated of recent years. But increased pay and a better class of warder are not to be had; "We must do the best with what material we can obtain." (Some day soon the crying evil of the inadequate pay, chronic overwork and miserable conditions of life of the warders in the Indian jails will reach a head, to judge at least from report after report which we have been called upon to review of recent years. The right type of man is the pensioned non-commissioned officer from an Indian regiment; but the conditions of service offered, although recently improved in some provinces, are hopeless. These men are badly housed,—often worse housed than are the prisoners; they are chronically overworked, in fact a whole night's rest in bed is the exception amongst them owing to shortage of cadre and sickness; often they are compelled to serve in most unhealthy areas. The recent Indian Jails' Commission made recommendations; but, as usual, the reply is that funds cannot be found.)

To some extent, the difficulty can be overcome by the selection of suitable convict warders and night-watchmen. This scheme, which has surely been in vogue in other provinces for some years, was introduced in Assam during 1923 and has worked well. The right type of

man to select is, in reality, the hardened habitual criminal himself. He is an exemplary prisoner whilst in jail, as a rule, and a strict disciplinarian. On condition that his efficiency earns remission of sentence, he does his work well; in fact in Burma, some Superintendents say that they prefer him to the paid professional warder!

Lastly, Colonel Bensley has a few remarks to make, and these much to the point, with reference to the necessity for jail officials to realise the tremendous influence which their own character and conduct may have over their prisoners. A high standard of personal living, strict discipline, and an absolutely just standard; these are what impress and teach the prisoner more than anything else, "I know the difficulties; I know the feelings of the harrassed jail official on a typical hot weather day, when he has been up since 5 a.m. and closes his jail at 6-30 p.m., and then does not know what may happen in the night. I know the worries he experiences, the pinpricks from the hardened habitual, the hundred and one demands he has to meet. An atmosphere of this kind does not encourage sympathy. I am afraid the whole case once more revolves around that vicious circle of financial stringency, but it is nevertheless the fact that economy in the administration of the jail department brings about innumerable hardships and misfortunes to all concerned, be they officials or prisoners." Will honourable members of Legislative Councils in a hurry to cut down all grants for prisons, please note? We fear not; they do not understand the first elements of the problems which they so light-heartedly tackle.

Turning to the statistical side of the report, the year shewed a definite decrease in the prison population, the year opening with 2,615 prisoners of all classes under confinement and closing with 2,424 prisoners in jail. The daily average of prisoners of all classes was 2,519 as against a figure of 396 more in 1922. Muhamadans numbered 41 per cent. and Hindus and Sikhs 52 per cent. In 1922, 0.21 per cent. of prisoners were under 16 years of age, in 1923 only 0.11 per cent., a welcome improvement. 74 per cent. of prisoners admitted belonged to the agricultural class. No less than 97 per cent. of prisoners admitted during the year were illiterate. There was a slight increase in the number of women sent to jail, and here conditions are wholly unsatisfactory, as frequently only a bamboo palisade intervenes between the male and female sides of the jails. 16 per cent. of the sentences given were for periods not exceeding one month, 44 per cent. for periods not exceeding three months, and 68 per cent. for periods not exceeding six months. (This approximately means that some 9 per cent. of prisoners admitted were habituals, who were present to contaminate the large volume of new first offenders and youthful offenders.) Owing to the return of prisoners from the Andamans, plans were proposed for the building of a new up-to-date jail at Jorhat, but financial considerations of course prohibited this. The number of persons detained under-trial underwent a substantial improvement, 4,709 as against 5,799 in 1922, a matter for congratulation in view of the interminable lengthiness of procedure in the Indian courts. "Civil," i.e., political prisoners, numbered only 2 at the beginning of the year and 1 at the close of it,—a striking change from the figures for recent years;—apparently the finances of the extreme Swaraj movement require replenishing.

The number of offences by prisoners dropped from 3,035 in 1922 to 2,690 in 1923. Major punishments—chiefly handcuffing—have perhaps been resorted to rather too much during the year under report, but the infliction of penal diets has been reduced. Only 6 prisoners were flogged during the year, or 0.08 per cent. of prisoners present, an incidence some 30 per cent. below that for any English public school. The number of prisoners who earned remission of sentence shewed a marked improvement upon the figures for 1922.

The conditions of the warder staff are deplorable. In the first place they are often badly treated by the subordinate jail officials; "they have been given a bad name and there is an end of them as far as jailors and assistant jailors are concerned." Their training has been woefully neglected; many are unable to turn out for inspections; in some jails only a small proportion have been partially trained for inspection, the rest being left untrained.

Vital statistics for the year reveal an unlucky one. The death rate, 23.82 per mille, was higher than that for the jails of any other province in India. But 43 per cent. of prisoners were admitted during the year in indifferent health, and 15 per cent. in bad health; figures considerably above the corresponding 42 and 12 per cent. for 1922. There was also a striking increase in the number of confirmed drug-takers admitted, no less than 29 per cent. of those admitted from the Assam Valley being habitues to opium, ganja, etc. On the other hand admissions to hospital shewed a decided drop, and the year was as a whole healthy. Deaths from among prisoners admitted with such hopeless conditions as advanced Bright's disease, chronic dysentery, gastric ulcer, advanced phthisis, Banti's disease, and advanced kala-azar help to swell the total. Sibsagar sub-jail had three deaths in the month of December, one from cerebral apoplexy, one from heart disease, and one from chronic sprue, which help to swell the total. Malaria accounted for 594 admissions on an average daily strength of 2,519; dysentery for 132, pulmonary tuberculosis for 20 admissions with 12 deaths, and pneumonia for 37 admissions with 12 deaths. A special tuberculosis ward, if not a special tuberculosis jail, is very badly needed in the province. All jails in the province are now provided with microscopes and there is no excuse for the late diagnosis of phthisis.

The total expenditure during the year upon the department, including the cost of new construction and repairs, amounted to Rs. 3,49,867—a sum nearly half a lakh less than in 1922. The average cost per prisoner, however, was Rs. 138-14-3 as against Rs. 133-14-1 in 1922. The net cash earnings amounted to Rs. 52,619-9-0, however, and the gross profit in the manufacture department to Rs. 75,782. In other words some 20 per cent. of the total cost of jail administration in the province is recouped by its productive activities.

Correspondence.

INTESTINAL STASIS AND CANCER IN INDIANS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With regard to your very interesting editorial comments upon my article with the above title in your issue of August, 1924, I feel after re-reading it carefully that I did not differentiate sufficiently between Indians of the cultured and upper classes and the illiterate villager following agricultural or pastoral pursuits.

I have reason to believe that Indians of the former class show little if any immunity from the ills to which the flesh of civilised man is heir.

Only a few days ago I saw a case which illustrates this point.

The patient was a Sikh, a forest officer who up to about two years ago had experienced fair health, though as his medical attendant wrote in his report of the case "constipation had been his life-long companion."

A forest officer spends little of his time in towns or civilised surroundings, the greater part of it is passed in the jungle and in the mountains. He is frequently forced to eat the coarsest of whole-meal atta, and such coarse fruits and vegetables as the local villagers are able to supply.

On the whole the last sort of diet on which to develop chronic constipation, if diet can do anything to arrest its acquisition.

Anxious to investigate this apparent anomaly I asked him to what he attributed his constipation. He replied that it commenced from the time when he first went to a school; he was so anxious to learn that he deliberately inhibited the calls of Nature in order that he might have more time for his studies. In the early morning there was always the rush to get away to school and the moment he had swallowed his food the same hurry to return to his books.

From this habit thus acquired in early life he never afterwards escaped.

When I saw him he was supposed to be dying from an inoperable malignant growth of the bowel, an exploratory operation having taken place some 5 months earlier.

The case is instructive in that it illustrates the fact that of all the factors contributing to produce this state inhibition is the most powerful.

It matters little how well balanced and physiologically perfect a diet may be if the calls of Nature are systematically disregarded, the result will be the same as though white bread and fish and chips were the daily fare.

The unlettered agriculturalist on the other hand has few temptations to neglect the calls of Nature; he has never been exposed to the rush and hurry of town life, never had to submit to the exigencies of school training, never had to wait his turn at the latrine, for, wheresoever he may find himself in field or jungle, his latrine is at hand.

The intention of my article was to approach the subject from the dietetic point of view. I can only speak for the Punjabi whose diet, of course, varies widely from that of the Bengali. I should imagine that the rice-eater would be more prone to suffer from stasis than the whole-meal wheat flour eater, but I have no first-hand evidence on the subject.

As regards the educated Punjabi his diet differs greatly from that of the illiterate villager; the town dweller and the babu class generally are coming more and more to the use of steel rolled Delhi flour and do not eat a great deal of raw fruit and vegetables.

Constipation seems to be very common amongst the clerical and town-dwelling class, but very rare amongst the country people.

Hence in recording cases of acute appendicitis in Indians very definite information is wanted as to diet, occupation, literacy, and previous medical history as regards the existence of constipation or not.

The same applies to the connected diseases such as gall-stones, gastric and duodenal ulcer, visceroptosis, etc.

If it is true, as I believe, that the uneducated villager enjoys an immunity from the group of diseases under discussion, then his habits are as well worth investigation as were those of those Gloucestershire milk-maids whose immunity from small-pox suggested a line of research to Edmund Jenner which led to the discovery of vaccination, the most momentous advance in preventive medicine which had been made up to that date.

I cordially agree that what is wanted are accurate figures, but in all such returns and reports I suggest that dietetic habits, literacy or the reverse, and social position should be clearly indicated.

This is, I fear, a long letter, but the importance of the subject must be my excuse.—Yours, etc.,

H. HALLILAY,
Lieut.-Colonel, I.M.S.

LAHORE,
17th November, 1924.

[Note.—We would welcome a draft of a proposed enquiry circular or card in connection with this subject, asking for all details required, for circulation to all

civil surgeons in India. The information thus collected, when analysed, might prove to be of considerable evidential value.—EDITOR, I.M.G.]

INTRAMUSCULAR QUININE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I see that the *Indian Medical Gazette* is once more reviving the stunt of the dangers and inutilty of intramuscular injections of quinine; in fact the crusade is so strenuous that we may soon expect to see the subject filmed, and the sadistic character of the exponents of this method of treatment shown up by lime-light. I am surprised that hitherto no one has had the temerity to break a lance on the subject, and I can only conclude the reason to be that the practice of intramuscular injections appears to be almost universal in malarial countries, but that those who use it have little to reply to theorists but continue to use it, satisfied with their clinical results. I have used intramuscular injections of quinine for nineteen years, being taught how to give them by Dr. Valentine, then medical officer to the North Cachar Tea Estates, and in that time I have given many hundreds, for in my early days I gave them much more freely than I now recognise to be necessary, and in no single case have I experienced any distressing result. Many hundreds also have been given by my subordinate staff, and I have never seen an injection go wrong, save when, against my instructions, it has been given in the arm. There are few operations, or treatments, which cannot be shown on occasion to result in failure or consequential damage, and such will be more frequent if treatment is carried out improperly. An intramuscular injection is a minor operation, and if not done correctly, or sepsis not properly guarded against, naturally, serious consequences may ensue. For instance, the arm should never be used, it appears to possess a peculiar liability to form a sloughing ulcer, and it is difficult to understand why injections are still given in that limb, for as far back as 1912 I was taught in the London School of Tropical Medicine that the practice was dangerous. I have always given injections in the gluteal region, choosing the highest point where the muscle is deep enough to sink the needle in, and the needle must not be the ordinary short hypodermic needle, but long enough to make sure of giving the injection well into the muscle. I have always used Burroughs and Wellcome's hypodermic "tabloids," and an ordinary 20 to 30 minim glass hypodermic syringe. In spite of laboratory experiments some years ago, in which the danger of tetanus and other evils was supposed to be proved, I think there were very few practitioners in Assam who did not continue to use the intramuscular method, being satisfied of its safety and the benefit derived, and that absorption was fairly rapid. I had confirmation of the last point in the case of a patient who, in three to four hours of each ten grain injection, developed a quinine rash. It appears to be generally accepted now that the action of quinine in malaria is not as simple as was at one time supposed, and if certain complex changes must first be effected, perhaps in the muscular tissue, it is open to doubt if intravenous injections have much, or any, advantage in rapidity of action. My impression is that cases receiving no further treatment relapse sooner after intravenous injections.

The ordinary case of malaria is amenable to quinine given in solution by the mouth, and the indiscriminate giving of injections of any kind is to be deprecated. They have their uses, in cases of heavy infection, when it is necessary to quickly control the disease, in cases of vomiting, especially the bilious type, in the case of those not absorbing the quinine, or not taking it as prescribed, and in some chronic cases, in which the extra stimulus appears to be helpful. Intravenous injections ought certainly to be tried in the cerebral form,—but does experience show that they are of much avail?

It is probable that there is little to choose between the two methods as regards efficacy. The intramuscular is more painful, but the pain is not great; the patient feels as if he was bruised, but this seldom lasts for more than a couple of days. I have known patients play polo on the next day but one. Intravenous injections have a pull in the matter of pain, but they require more care and skill in their administration, and the risks are undoubtedly greater. It has to be remembered that the treatment of malaria in India is largely carried out by comparatively untrained and unskilled men; it is difficult to realise the ignorance of asepsis that obtains, and I think most of us, in spite of gruesome pictures, would infinitely prefer, if the occasion arose, to be given an intramuscular injection, by such, in preference to an intravenous. A mishap with the latter and one might not live to be photographed!—Yours, etc.,

R. A. MURPHY.

LUSKERPORE TEA ESTATE,
CHANDPORE BAGAN P. O.,
SOUTH SYLHET,
18th October, 1924.

[Note.—We publish Dr. Murphy's letter with much pleasure on the principle of *audi alteram partem*. With regard to the question of tetanus, it does not rest solely on Sir David Semple's work. A very sad tragedy which occurred several years ago in Central India was the death from tetanus of a young English girl, just out from Home, a few days after an intramuscular injection of quinine. The injection had been prepared at a British Station Hospital with every possible precaution taken; but investigations shewed that tetanus spores were present in the distilled water used, and had probably got into it from the straw packing in which the bottles of distilled water had been received by the hospital.

We agree with Dr. Murphy that the arm is an entirely unsuitable site. Not long ago an adult female Anglo-Indian patient was admitted to the Carmichael Hospital for Tropical Diseases in Calcutta. Having gone down with fever she had consulted a practitioner who had given her a course of intramuscular injections of quinine into the deltoids, without apparently even examining the blood. On admission there was a large and foul ulcer in the right arm, at the bottom of which the humerus lay exposed; in the left deltoid an abscess was developing. The case turned out to be one of typhoid fever, and ultimately proved fatal; the fatal issue being almost certainly hastened by—if not due to—the exhaustion of the patient's strength by the prolonged suppuration.—EDITOR, I.M.G.]

THE PSYCHOLOGY OF FREUD.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I have read with much interest the correspondence appearing in your journal on the psychology of Freud. Lieutenant-Colonel A. W. Overbeck-Wright has a distinguished record in alienist work, and his remarks against the Freudian standpoint certainly deserve a fair consideration. Freud's doctrines have not received universal recognition as yet, and there are bound to be two sides to the question. It is, therefore, easy to quote authorities either favourable or otherwise, according to the leanings of a particular writer.

To condemn a controversial point, something more substantial than the mere quoting of authorities is necessary. One is disappointed to find that Colonel Overbeck-Wright's arguments consist only of vague assertions; "condemned by the majority of British alienists," "discarded by all reputable psychiatrists," etc. The "public denouncement by the British Medical Association" is no better. By the way, one becomes curious to know on what occasion this august body passed such a weighty judgment. Even if the whole world stands

against a doctrine, it does not necessarily prove its fallacy.

One looks in vain for a criticism based on personal experience of the subject in Colonel Overbeck-Wright's letter. Most of the critics denouncing psycho-analysis belong to the armchair type. It is, of course, presumptuous on my part to refer such a distinguished alienist as Colonel Overbeck-Wright to the history of hypnotism with which he is no doubt familiar. Hypnotism was repeatedly condemned by successive scientific commissions in different parts of Europe, and there were many distinguished persons on them. In spite of all hostile criticisms, hypnotism has held its own.

Psycho-analysis has been in the field now for more than a quarter of a century, and there have been adverse critics who have foretold its end before Colonel Overbeck-Wright, but much to the chagrin of all these prophets, psycho-analysis is still going strong. Colonel Overbeck-Wright in the course of his alienist work must have seen persons foretelling the end of the world and daily expecting to see their prophecy fulfilled. The wish in such cases is father to the thought, and although one may sympathise with such a person's mentality, one may as well be excused for refusing to set any value on such assertion.

There is, however, no reason to become impatient of Colonel Overbeck-Wright's attitude. The history of all religious and political movements amply proves that the most violent critic is apt to become the most ardent convert.—Yours, etc.,

G. BOSE, D.Sc., M.B.,
President, Indian Psycho-Analytical Society,
Lecturer in Abnormal Psychology,
University of Calcutta.

"PHENOLAINÉ."

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to an enquiry regarding 'Phenolainé' in the July number of the *Indian Medical Gazette*, I have to inform you that the drug is a powerful liquid local anæsthetic, and can be employed in operative work of every description.

It can be had from Messrs. W. Martindale, 10, New Cavendish Street, London, W. in 1 dr. and 1 oz. bottles.—Yours, etc.,

VALLABHDAS N. MEHTA, L.M. & S.

VIRAMGAM:
2nd November, 1924.

CHUNAM CANCER.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the report on the surgical work at the Government General Hospital, Madras, published in the October issue of your journal, Colonel Bradfield evidently lays much stress on the part played by *chunam* in the causation of cancer of the cheek and lower jaw in South Indians.

The local irritant effects of *chunam* should not make us lose sight of the fact that there is another irritant which contributes an equal share, if not more, to the causation of the said cancers. I refer to tobacco. In the majority of such cases of cancers, on careful enquiry there is invariably a history of the tobacco habit. The tobacco, either alone or more usually with betel leaves smeared with a little *chunam* is taken chewed, and retained between the cheek and the lower jaw. Some people retain this bolus for hours together every day. Thus ample opportunity is offered for the tobacco to work its mischief and exert its irritant action

on the delicate mucous membrane of the cheek and lower jaw for hours together every day. So it is tobacco that comes more in contact with the cheek than the *chunam*, and the blame should fall more upon the tobacco than on the *chunam*. Moreover, the *chunam* does not come into direct contact with the cheek, inasmuch as nobody swallows pure *chunam* as it is,—much less keeps it in contact with the cheek. *Chunam* is used by smearing a little quantity of it on the betel leaf or very rarely on the tobacco itself. There is no likelihood of the *chunam* coming or remaining in direct contact with the cheek for a sufficiently long time. If, as Colonel Bradfield claims, the *chunam* were entirely to blame, then, considering the fact that almost all Indians chew betel leaves smeared with *chunam* at least twice a day, the incidence of cancer of the cheek and the lower jaw should be universal or at least very high.

I do not mean to say that *chunam* does not or cannot cause cancer, nor do I say that all tobacco users get cancer of the cheek. I simply wish to point out that it is tobacco that comes more in contact with the cheek and the lower jaw, and not the *chunam*, and so the probability of tobacco being the causal agent more than the *chunam*. As regards the local irritant properties of tobacco, this needs no proof.—Yours, etc.,

G. RAGHUNATHA RAO, L.M.P.

PERAMBALUR, TRICHINOPOLY DISTRICT:

INTRAVENOUS AIR EMBOLISM.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I have read with interest Dr. Hari Prasad's letter in the October, 1924, issue of the *Gazette* on page 530 regarding *intravenous air embolism*. His letter is both instructive and suggestive, but he has not been able to find a satisfactory explanation of the harmlessness of small volumes of air injected into the vein. This implies a pre-formed idea that the entry of air into a vein is harmful. Now one knows the affinity between venous blood and oxygen, as evidenced in the lungs. Through intervening cells oxygen that is inspired is taken up by the venous blood, which is thus naturally purified. Another example one may cite is that one sees daily on the operation table venous blood spilled, yet if one were to take careful note, it will be seen that gradually the dark-coloured venous blood acquires a bright red colour, and there is no difference at the termination of the operation between the two different "kinds" of blood. In the same way, when air enters a vein, the impure blood readily takes up the oxygen and some benefit is thus derived, but as air also contains gases unsuitable for absorption by the blood in large quantities, besides gross impurities, it would not be safe to employ intravenous air injections as a remedy. But one might in certain cases employ oxygen, slowly from a generator through the graduated container of a Junker's inhaler in order to regulate the supply. And it is with this view I make the suggestion for one, such as Dr. Hari Prasad who has the opportunity to investigate. To my mind only asphyxial cases, such as cases of opium poisoning, colubrine snake poisoning, etc., would be suitable. Oxygen has been successfully employed subcutaneously into the abdomen, and into joints, then why not slowly into the circulation. Hydrogen peroxide 2 ozs. in 8 ozs. saline might also be tried, but here again *very slowly* so as to give the generated oxygen time to be taken up by the blood.

A stream or river during its flow dissolves oxygen from the atmosphere. Is it unreasonable to expect the venous flow to chemically combine with oxygen supplied to it? Experiment only will decide.—Yours, etc.,

J. E. LEONARD CHINAL, M.D., D.T.M., L.M.

MONGHYR,
14th October, 1924.

INDIGENOUS INDIAN DRUGS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—At a recent meeting of the Advisory Board of the School of Chemical Technology, Calcutta, the Board noted with satisfaction the progress of the School in respect of the following matters:—

(1) *Technological Education and Drugs' Investigation*.—The series of articles lately issued by the School in connection with technological education suggested various technical lines, including the one of scientific investigation and manufacture of important medicinal herbs and drugs, a specialised subject on which a pamphlet was issued by this School in 1919, showing for the first time the importance and possibilities of the new work and the necessity for co-operation of pharmacologists, chemists and bacteriologists. Recently in a leading newspaper there were long communications on the subject from the Calcutta School of Tropical Medicine and a medical practitioner, the latter going so far as to suggest the creation of a chair in the Calcutta University in commemoration of the memory of the late Sir Asutosh Mukherjee. Both the communications apparently assumed that they were the first to give this new idea to the world, although the pamphlet referred to was appreciatively reviewed by all the leading medical journals in India and abroad so long ago as 1919 (vide *Indian Medical Gazette*, editorial, March, 1919, pp. 101–102).

(2) *Diabetes, Tuberculosis and Leprosy Work*.—The School's work in connection with *Cephalandra indica* for the treatment of diabetes was noticed in the January 26th issue of the *Pharmaceutical Journal*, London, and an order was received last month from an American firm for the supply of this drug, which was promptly complied with. The work on *Allium sativum* which was published in 1922 in several medical journals, including the *Indian and Eastern Druggist*, London, is meeting with some success, there being orders from all over India for supply. The last but not the least is the work since 1917 on *Hydnocarpus wightiana* (published in the June, 1923, issue of the *Antiseptic*), although its present sponsors in their campaign against leprosy do not consider it necessary to refer to it.

(3) *Draft Bill to control dispensing and drug adulteration*.—The School has been working very hard since 1919 for a Pharmacy Act for dispensing to be carried out only by qualified persons, as in most civilised countries, and for a Food and Drugs Act to prevent the widespread adulteration of foodstuffs now obtaining in India. The latest information was collected and embodied in a draft bill which would have been moved in due course by Dr. Moreno, but for the present prorogation of the Bengal Council. It is noted that there has been a recent awakening amongst the industrialists and manufacturers in Delhi for the establishment of an up-to-date laboratory for analytical purposes to facilitate the extension to the imperial capital of the Punjab Food Adulteration Act. It is, therefore, all the more necessary that the second city of the British Empire should maintain her lead in the matter by encouraging the public to become sufficiently interested in the subject and to avail themselves fully of the opportunities offered by the Calcutta School of Chemical Technology.—Yours, etc.,

J. C. GHOSH,

Hon. Secretary, School of Chemical Technology, Calcutta.

CALCUTTA,
September 15th, 1924.

A DISCLAIMER: COLLOID OF CALCIUM.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the October number of the *Indian Medical Gazette* there appears on page XI an advertisement of a substance called Collo-Calcium produced by the Anglo-French Drug Co. (Eastern), Ltd., in which a quotation

appears under my initials from an article published by me in the *British Medical Journal*, January 14th, 1922, p. 53, under the title "The Treatment of Tuberculosis with Colloid of Calcium." My article was based on experiments made with colossal calcium prepared by the Crookes' Laboratory, London, which was made sufficiently clear in the concluding paragraph which runs:—"In conclusion, I wish to express my thanks to Sir Malcolm Morris for the interest he has taken and the encouragement he has given me during this investigation, and to Mr. J. Ward, chief chemist to the Crookes' Laboratories, for preparing the drug and for much valuable information concerning its properties." It was with reference to this particular preparation that my article was written and it is most unwarrantable for a firm to advertise something which is completely different in every way and lead the unwary to infer that they were getting the real thing. That this preparation of Crookes' is a most valuable therapeutic agent when given correctly I have no reason to doubt, but I have not the slightest knowledge as to the therapeutic value of the drug advertised by you; I should therefore feel obliged if you will publish this disclaimer. No doubt this advertisement crept in without a correct knowledge of the true facts of the case.—Yours, etc.,

EDWARD E. PREST, M.A., M.D. (Cantab.),
Medical Superintendent, Ayrshire Sanatorium and
Consulting Physician to the Ayrshire Joint
Tuberculosis Committee.

November 10th, 1924.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel J. R. J. Tyrrell, Agency Surgeon, Bundelkhand, is appointed to officiate as Political Agent in Bundelkhand, in addition to his own duties, with effect from the 30th October 1924 and until further orders.

His Excellency the Chancellor of the Delhi University is pleased to appoint Lieutenant-Colonel G. D. Franklin, O.B.E., I.M.S., Civil Surgeon and Chief Medical Officer, Delhi, to be a member of the Academic Council of the Delhi University.

Major P. F. Gow, D.S.O., M.B., I.M.S., officiating Civil Surgeon, Rajshahi, is appointed to act as the Civil Surgeon of Darjeeling, with effect from the 25th October 1924, *vice* Lieutenant-Colonel A. H. Proctor, I.M.S., granted leave.

Major C. H. Smith, I.M.S., is appointed to officiate as an Agency Surgeon, with effect from the 18th April 1922.

In modification of the orders already issued, Major H. King, I.M.S., officiating Assistant Director, Central Research Institute, Kasauli, is appointed temporarily to act as Director, Pasteur Institute of India, Kasauli, with effect from the afternoon of the 2nd October 1924. He will, in addition, be in charge of the statistical work of the Assistant Director, Central Research Institute, Kasauli.

The services of Major G. T. Burke, M.D., I.M.S., are placed temporarily at the disposal of the Government of the United Provinces, with effect from the date on which he took over the officiating appointment of Professor of Medicine, King George's Medical College, Lucknow.

Captain H. S. Anand, I.M.S., is attached as Advisory Chemist to the Medical Stores Depot, Madras, with effect from the forenoon of the 18th October 1924, *vice* Captain A. F. MacCulloch on leave.

The services of Captain O. R. Unger, I.M.S., are placed temporarily at the disposal of the Government of Bihar and Orissa for employment in the Jail Department, with effect from the date on which he assumes charge of his duties.

The King has approved the transfer to the temporary non-effective list of Captain Mahdo Prasad, M.B., I.M.S., with effect from the 3rd October 1924.

LEAVE.

Lieutenant-Colonel A. H. Proctor, I.M.S., Civil Surgeon of Darjeeling, is allowed leave for 6 weeks, with effect from the 25th October 1924.

In modification of the orders already issued, Lieutenant-Colonel W. W. Jendwine, C.M.G., I.M.S., Civil Surgeon, Simla West, is granted leave for 2 months and 21 days combined with study leave for 2 months and 28 days, with effect from the afternoon of the 8th October 1924.

Lieutenant-Colonel E. O. Thurston, I.M.S., Civil Surgeon, Hooghly, is allowed combined leave for 28 months, with effect from the 1st February 1925.

Major T. L. Bomford, M.D., I.M.S., was on study leave for a total period of 8 months and 8 days, viz. (1) from the 25th September to the 22nd December 1922, (2) from the 14th January to the 24th March 1923, and (3) from the 24th September to the 22nd December 1923, for which lodging allowance was paid to him by the India Office.

Captain C. de C. Martin, I.M.S., is appointed temporarily to the Medical Research Department and posted as a supernumerary officer at the Central Research Institute, Kasauli, with effect from the date he takes over charge.

Captain J. C. De, I.M.S., has been granted by the High Commissioner for India leave for a further period of 6 months in extension of the combined leave granted to him.

PROMOTIONS.

Lieutenant-Colonel to be Colonel.

Robert Welland Knox, D.S.O., M.B., F.R.C.S., *vice* Colonel Harold John Kinahan Bamfield, D.S.O., K.H.P., promoted to the rank of Major-General, with effect from the 24th September 1924. Colonel Knox's tenure of appointment will count from the 3rd October 1924.

The undermentioned Captains (now Majors), Indian Medical Service to be Acting Majors whilst holding appointments with the Mesopotamian Expeditionary Force:—

1. C. J. Stocker, M.C., M.D., from 4th January 1918 to 9th April 1918 and from 19th December 1918 to 23rd June 1920.

2. A. A. C. McNeill, M.B., from 4th August 1918 to 1st May 1919 and from 12th June 1919 to 31st January 1920.

Major (now Lieutenant-Colonel) W. F. Harvey, C.I.E., M.B., I.M.S., to be acting Lieutenant-Colonel from 2nd October 1916 to 13th December 1916 whilst employed as Assistant Director of Medical Service (Sany.) in Mesopotamia.

RETIREMENTS.

The King has approved the retirement of Major-General B. H. Deare, C.I.E., K.H.S., I.M.S., with effect from the 27th August 1924.

Lieutenant-Colonel W. G. Liston, C.I.E., M.D., I.M.S., with effect from 24th September 1924.

Lieutenant-Colonel J. W. Grant, M.B., I.M.S., with effect from 5th October 1924.

NOTICES.

LONDON MEDICAL EXHIBITION.

THE exhibit of Messrs. Burroughs Wellcome & Co., in previous years, is notable for several important additions to the varied products of the firm. The exceptionally high standard of 'Wellcome' brand insulin has been raised by new methods of manufacture, while the price has been considerably reduced. The availability of insulin is enhanced by the production of 'Tabloid' hypodermic insulin hydrochloride, which ensures the

administration of a precise dose of insulin, obviates risk of deterioration, and facilitates use by nurse, or even patient, under medical direction.

The 'Soloid' urine-sugar test case which is shown, is designed further to facilitate the examination of diabetic urine. This small portable case contains all the essentials for the qualitative determination of sugar. The 'Soloid' Benedict test supplies a simple method of performing this delicate test which will be welcomed by the physician. With the 'Soloid' products the test is so easy to carry out and so plain in its indications that diabetic patients can make daily examinations of their urine if the physician so desires.

Among the gland products is exhibited 'Tabloid' parathyroid gland. Inspection, checked by microscopic section, ensures the production of authentic parathyroid, thereby safeguarding the medical profession. Various stages in the preparation of gland products are shown, emphasising the fact that the whole gland substance, not extracts are used.

The activities of the firm are further shown by the 'Wellcome' sera and vaccine produced at the Wellcome Physiological Research Laboratories for which Burroughs Wellcome & Co. act as distributing agents. Medicinal plants grown on a commercial scale at the 'Wellcome' Materia Medica Farm, Kent, are shown in a remarkably healthy condition. The importance of the farm from the point of view of the therapeutic activity of the firm's products will readily be realised.

The successful use of 'Iodicin' has led to the production of 'Ethidol' a colourless non-irritating liquid, containing 20 per cent. of iodine, for intraglandular injections and inunction. The external use of 'Ethidol' in conjunction with the internal use of Iodicin enables the iodides to be intensively exhibited.

Bismuth is now placed alongside arsenic and mercury in the treatment of syphilis, and 'Bicreol' bismuth cream, which has a creo-camphor base, appears to be an ideal product for intramuscular injection.

'Wellcome' brand chemicals are represented and many 'Tabloid' and 'Soloid' products—some recently introduced and others well-known the world over—are shown. As usual 'Tabloid' medical equipments and first-aid outfits are displayed, additional interest being added by the fact that the "round the world" flights, American and British, have been equipped with these admirable outfits.

The whole is of great interest to the profession, and proves that Burroughs Wellcome & Co., by virtue of their pioneer and research work, remain ever in the forefront of medical progress.

DIMOL.

Of the evils ascribed to intestinal stasis as the primary aetiological agent there is no end, from puerperal eclampsia and premature senility to infantile convulsions. Whilst those who ascribe some half of the ills to which mankind is heir to this condition, and claim that its cure would eradicate the cancer problem and several others, yet there can be no doubt as to its really baneful influence in inducing diseased conditions in the tropics. Thus in the treatment of the "post-dysenteric abdomen" we often have a picture of mingled visceroptosis, endocrine deficiency and chronic intestinal stasis, replaced by occasional days of intermittent diarrhoea.

Under such circumstances, the medical practitioner seeks for (a) first, some safe and non-irritant intestinal aperient, which we consider that he will find in some form of purified liquid paraffin, which is about the only aperient permissible in conditions of chronic colitis in the tropics; and, secondly, (b) for some really efficient intestinal antiseptic. For "Dimol," the chemical constitution of which is stated to be dimethylomethoxyphenol, it is claimed that it will sterilise the duodenum of bacteria on administration by a duodenal tube, and that it will render the effluent from a Plombières douche to which it is added sterile upon plating 1 c.c. on a

Petri dish of culture medium. Many authorities, including, of course, Sir Arbuthnot Lane and even Frankel, have stated the enormous advances which may result from the discovery of a really efficient intestinal antiseptic; but, one by one, those which are introduced appear to fade and die away.

We assert no claims for this product, which we have unfortunately not fully tested, other than those put forward by its agents, the Anglo-French Drug Co. Recently we have seen a case of sprue in a European male patient who had been for years under many different forms of treatment, but who claimed that no other drug had given him such satisfaction and freedom from all symptoms, including that of sore tongue. A report in the *Lancet* of the 24th February, 1923, states that "a lavage solution is capable of killing dysentery bacilli in 2½ minutes." At least the drug appears to be worth trial in all cases where intestinal stasis exists in any of its protean manifestations. The drug is put up in the form of "pulverettes" in tins of 500 at 9s. each; in syrup; as a powder for colonic lavage; as a dusting powder, insufflation powder, and ointment at reduced rates for large hospitals. The prices quoted in the published price list, however, do not include freight and insurance, import duties and landing and clearing charges.

The testimony borne as to the efficacy of the drug by several workers is encouraging. If there is here an intestinal antiseptic of real and proved value, it will be of very considerable interest and importance in medical practice in the tropics.

EDINBURGH EXTRACT OF MALT WITH COD-LIVER OIL.

A PREPARATION which is at least very palatable, and which the makers guarantee to be made from pure materials, is Messrs. Harkness, Beaumont & Co.'s (Leith, Edinburgh) extract of malt with cod-liver oil. It is stated to be free from glucose, dextrinised potato starch and similar adulterations. A patient who was placed on it—a case of suspected phthisis—gained weight very satisfactorily. The Indian agent is R. Krishnaswami, P. O. Box No. 500, Bombay.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints of the literary pages of the "*Gazette*" gratis, if asked for at the time of submitting their manuscripts.

REPRINTS OF THE ARTICLE CONCERNED (ONLY), IN PLACE OF REPRINTS OF THE WHOLE OF THE LITERARY MATTER OF THE ISSUE, CAN BE SUPPLIED ON PAYMENT IF ASKED FOR AT THE TIME WHEN ARTICLE IS SENT IN. BUT AS THESE HAVE TO BE MADE UP SEPARATELY, THEY ARE NECESSARILY DELAYED.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, MESSRS. THACKER, SPINK & CO., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

TYPHUS-LIKE FEVER, PROBABLY TICK-TYPHUS, IN CENTRAL INDIA.

By J. W. D. MEGAW,

LIEUT.-COLONEL, I.M.S.,

Director and Professor of Tropical Medicine, Calcutta School of Tropical Medicine and Hygiene;

F. B. SHETTLE, O.B.E.,

MAJOR, I.M.S.,

O. C., Indian Station Hospital, Saugor,

and

DHIRENDRA NATH ROY, M.B. (Cal.),

D.T.M. (Cal.),

Assistant Professor of Entomology, Calcutta School of Tropical Medicine and Hygiene.

THE cases described in this note are of interest as furnishing fresh evidence of the occurrence in India of a typhus-like fever which is identical with or closely related to the spotted fever of the Rocky Mountains. The senior writer has already discussed Indian cases of fever of this type, in the *Indian Medical Gazette*, in articles published in Vol. LII, 1917; Vol. LVI, 1921; and Vol. LIX, 1924.

He also summarised the existing knowledge of the typhus-like fevers which occur among persons living in close association with the life of the wilds, and brought forward evidence which points to the occurrence of these fevers in South Africa, Nigeria, Australia and Sumatra. In most of these cases the infection is probably carried by a tick from an animal reservoir, but in others the mite is probably the vector. The cases now described were brought to the notice of the senior writer by Major Shettle, I.M.S. The description of the cases, which was given by Major Shettle in his letter of February 1st, 1924, is as follows:—

Equitation School,
Saugor, C. P.

Dear Colonel Megaw,

I believe that some time back I remember reading an article of yours about a fever resembling the spotted fever of the Rocky Mountains. Last year here I had three curious cases of fever which no one could diagnose and I said that I thought that they might be of the dengue group, but much more resembled the tick fever of the Rocky Mountains. There are now some manoeuvres on here and I have had several more cases. They all run to a type and I have not heard of any such occurring elsewhere amongst the troops in this district. No one who has seen them can put a name to them.

They have all occurred in persons who have been exposed to tick bites in the jungle around here.

I have seen altogether two cases amongst Indians, about a dozen in European soldiers, and two in officers. I have to-day admitted Colonel —, R.A., for the same disease. The blood of all of the cases is negative to malaria and spirochaetes and nothing can be noted except perhaps leucopenia.

The relative count sometimes shows an increase of mononuclears. The symptoms are all the same and

consist of acute muscular pains and joint pains, headache, pain behind the eyes, furred tongue, sometimes congestion of the conjunctivæ and throat, vomiting once or twice at the commencement, bleeding from the nose and occasionally a little diarrhoea at the commencement. The pains are very like those of dengue and vary considerably with the severity of the case.

There is sometimes an attack of palpitation and the heart sounds become irregular and muffled. In two cases there has been a little temporary tympanites; otherwise, with the exception of one case, abdominal symptoms are absent. The spleen is a little enlarged in most of the cases.

All the symptoms gradually disappear with the fading of the rash, which generally stays out after the temperature has come to normal. The rash appears on any day up to the fifth or sixth day, as far as I can make out; is rubecular in character and commences on the trunk and extensor surfaces of the limb, particularly on the backs of the hands and soles of the feet and palms of the hands. In mild cases it is very discrete and in severe cases the reverse; it spreads to the face and in the end covers the body.

It lasts in some cases up to 20 days and in the end fades with a very slight desquamation which is not general. If seen after some time it rather looks purpuric, so much so that one officer diagnosed a case as purpura rheumatica, and another case was diagnosed as smallpox.

The fever varies in duration, but generally lasts from 12 to 17 days. It commences about 102° or 103° and then comes down and there are daily remissions, some cases coming to normal daily, so that the chart resembles malaria. The rises gradually get less until the temperature reaches normal; 50 per cent. of the cases are mild. There have been no deaths.

At present I have seven cases in hospital, all in various stages. I have consulted the local Civil Surgeons both last year and this and they cannot put a name to the disease, nor have they seen any locally. The blood has been sent for the Weil-Felix test and no reply has been received yet. But they are not typhus, and I have seen a lot of typhus in India on the frontier. The reports for the typhoid group are not in favour of that disease. I have been in India 20 years and have seen nothing like it before. I wonder if you would agree with my provisional diagnosis?

I think the cases are very well worth seeing and investigating. I am up to my ears in work and have no time. There are no lice on the men's clothes and I think I would have had more cases if it were due to that cause. Bugs have not been found. The rash is not irritating and has not been noticed by the patient in several cases until it has been pointed out or become pronounced.

Yours sincerely,
(Sd.) F. B. SHETTLE,

Major, I.M.S.

The following account is written by the senior author, who observed the cases on the 9th and 10th of February, 1924, but most of the detailed observations are due to Major Shettle, Captain Dotivala, I.M.S., and the junior author.

The senior author is indebted to Dr. Strickland, Professor of Entomology of the Calcutta School of Tropical Medicine, for placing Dr. Roy at his disposal for a detailed study of the cases and for many valuable suggestions and criticisms in connection with the work. The main features of the cases have been recorded in the form of charts, tables and illustrations, so that the explanatory text is brief.

All the cases occurred among a body of more than two thousand men who were engaged in manœuvres in two camps, each situated about ten miles from Saugor in Central India, and about twenty miles from each other.

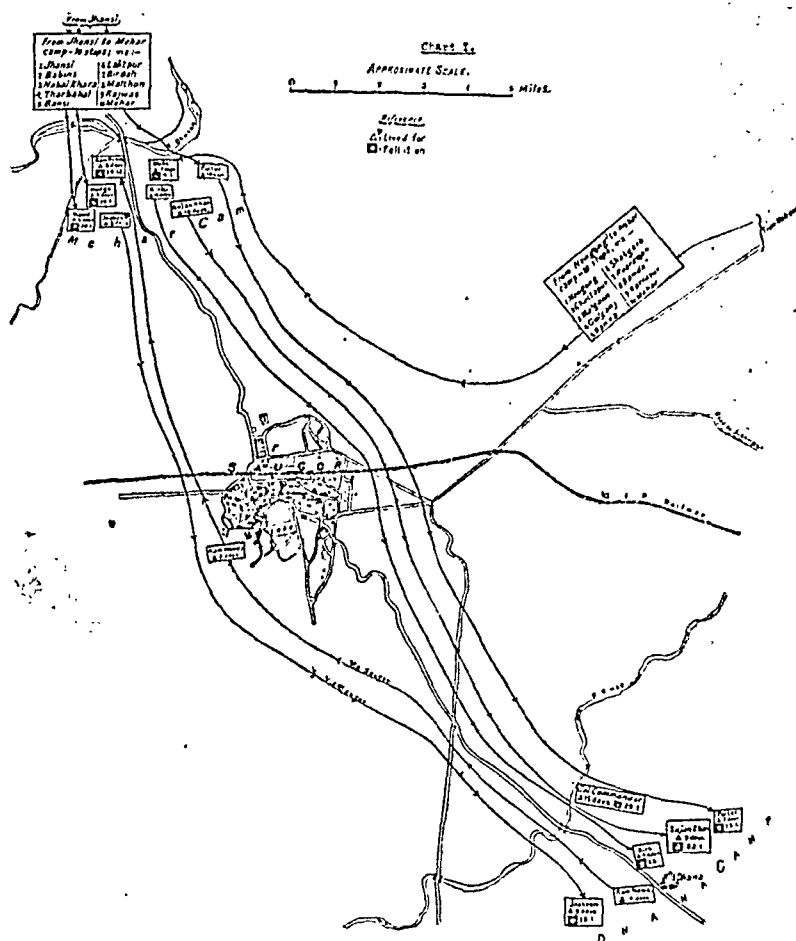

Saugor is a town of about 40,000 inhabitants, the town and the surrounding country being at an elevation of between 1,500 and 2,000 feet above sea-level. The affected troops were living in tents in two camps, which were situated in very sparsely inhabited country consisting chiefly of uncultivated scrub and jungle, so that there was little contact between the patients and the inhabitants of the place. In Chart I, is shown the approximate situation

The incubation period of the disease could not be determined in any case, so that it is not possible to be certain of the exact locality in which any patient contracted the infection. The possibilities in this connection are shown in Chart II.

From the data shown in this chart it appears to be likely that infection was not contracted in any one spot but in both of the camps and also probably on the route along which the troops marched on their way to the camps. In the case of each of the men who took part in the manœuvres the chance of infection was small, as only about one person in two hundred was attacked.

No evidence could be obtained of the

CHART I.

of the tents in which each case occurred and the previous movements of each patient are given for three weeks previous to the onset of the disease. No evidence could be obtained of contact between any two of the patients, and the incidence of the cases strongly suggests a "chance distribution."

Although the conditions in the camps were favourable to person-to-person infection, no other occupants of any tent in which a case occurred were attacked, and altogether there appeared to be no tendency to contact infection.

occurrence of any cases of the disease in the localities in which the patients lived and it can be stated with reasonable certainty that there was no epidemic of any such disease either at the time or previously.

The manner of occurrence of the disease suggests that it is liable to attack persons leading an open-air life and coming in contact with the conditions of the wilds. In this respect the disease resembles the spotted fever of the Rocky Mountains and the typhus-like fever of the Kumaon Hills described by

PLATE I.

Plate I.

Gnr. WALLER.
(On 17th. day of illness.)

McKechnie as typhus and by the senior author as tick-typhus. There is also a close resemblance to this disease in the clinical characters of the cases. The possibility of the disease being louse-borne typhus was carefully inquired into, but this disease could be excluded, not only on epidemiological grounds but also by the complete absence of lice, by the negative

any pronounced lymphocytosis, such as is so striking a feature of the mite-borne cases.

2. Conjunctivitis and sore throat were of more frequent occurrence among the cases in this series than in the cases of typhus-like fever recorded from other parts of India in which there was evidence of conveyance by ticks, but conjunctival congestion and bronchial

Weil-Felix reactions (only two out of seven cases showed agglutination in dilutions up to 1-80, the others being completely negative), and by the clinical features, which are much more like those of the Rocky Mountain fever than those of louse-typhus. The only reasons for doubting that ticks were responsible are:—

1. No ticks were seen by any of the patients on his person, though there were ample opportunities for their being bitten by the ticks which were common in the jungle within the probable incubation period. In this respect the disease differs from many of the cases of Indian tick-typhus which have come to my notice and in which there was a history of tick bite within a few days previous to the onset. In the Saugor cases the tick may have bitten and fallen off without being observed; or there may conceivably have been some other vector such as a mite. There was no evidence of the existence of biting mites in the locality and the disease appears to differ from the mite-borne typhus-like fever of Japan and Sumatra in the absence of any local ulcerated sore in any of the cases, in the absence of any local lymphadenitis and also in the absence of

catarrh are conspicuous features of the Rocky Mountain tick-typhus.

3. The temperature charts differ from most of those seen in the presumed cases of tick-typhus in India in showing greater daily remissions, almost amounting to intermissions in some of the cases. These differences may be merely variations such as usually occur in different groups of cases of the same disease, or they may indicate that the disease is a distinct variety though belonging to the same disease group.

It appears to be probable that the cases belong to the tick-typhus group, but in the absence of direct evidence of the bite of this arthropod we are not justified in excluding other possible vectors.

An attempt was made to obtain evidence of the nature of the virus by inoculations of the blood of patients into guinea-pigs: unfortunately the animals were inoculated with blood obtained towards the end of the attack or after the attack. The guinea-pigs were carefully observed by Major Knowles, Professor of Protozoology at the Calcutta School of Tropical Medicine, but no evidence of the

presence of any active virus was obtained. A search for ticks and mites of the jungle was arranged for, but was not carried out as the

insect collector who was engaged for the work decamped without making any serious effort to collect them. When opportunity offers

further efforts in this direction will be made. The only evidence of the nature of the disease is of a general epidemiological and clinical nature, but it is certain that the cases were of a typhus-like fever which probably has as its reservoir an animal of the wilds and the

GUNNER WALLER.

vector is probably a tick or other biting arthropod of the wilds. The persons likely to be infected are persons camping or marching in the jungle or open country of certain parts

of India, there is no evidence of person-to-person infectivity. The absence of evidence of the occurrence of the disease in persons in the infected localities is not regarded as proof that the disease does not occur among them, it is very likely that it does occur in the form of sporadic cases affecting chiefly the children and that most of the adults are immune owing to attacks in childhood. When it is borne in mind that the disease even in Europeans has not been recognised till recently, it is not surprising that it has not attracted attention among the dark-skinned inhabitants of places where fevers are regarded as matters of commonplace occurrence not calling for any special notice. It is suggested that the cases should be classed as "jungle typhus-like fever, probably tick-typhus" as a provisional measure until more evidence of the vector has been obtained; if the vector should be proved to be a tick the most suitable name will be "tick-typhus." The disease will be discussed in a separate paper by the senior author who has obtained a good deal of further evidence of the occurrence of a tick-borne typhus-like fever in other parts of India.

The photographs, coloured drawings and charts of the cases ought to enable others to recognise the disease, and it is hoped that any cases which are observed will be recorded.

The outstanding clinical features of the disease are clearly shown by the coloured plate, by the temperature charts which have been kept not only in the nine cases recorded, but also in two similar cases which occurred in the same camps a year previously and by the comparative tables. For a comparative table of the features of louse-borne typhus and of the other typhus-like fevers reference may be made to the article in the *Indian Medical Gazette* for February 1924, in which, however, there is a printer's error by which the mortality of louse-typhus is shown as 3 to 6 per cent. instead of 3 to 60 per cent.

INDIAN TICK-TYPHUS.

By J. W. D. MEGAW,

LIEUT.-COLONEL, I.M.S.,

Director and Professor of Tropical Medicine, Calcutta School of Tropical Medicine and Hygiene.

SINCE the paper, in the *Indian Medical Gazette* of February 1924, on the typhus group of fevers was published, a good deal of further evidence has been obtained which points strongly to the existence of a typhus-like fever in India which is conveyed by a tick. This fever is so similar in its epidemiology and symptomatology to the spotted fever of the Rocky Mountains that I should not be justified in giving it any other name, but for the obvious inapplicability of the term "Rocky Mountain Fever" to a disease occurring in India. The term "spotted fever"

has been applied to so many diseases and is so lacking in descriptive quality that it seems best to change the name altogether rather than to retain an unsuitable part of the title. The term "tick-typhus" has the great advantages of indicating the vector of the disease and the disease group to which the affection belongs. The close relationship which obviously exists in the clinical manifestations and the pathological findings of louse-typhus and the tick-borne disease amply justifies the inclusion of the two diseases in one group, just as tick-borne relapsing fever is included in the same group as the louse-borne disease. A well recognised designation of a disease should not be discarded lightly, but in the present case an absolute necessity arises for the change of one part of the name, and as the other part is unsuitable a good opportunity arises for an improvement in the nomenclature.

The fresh evidence of the existence of tick-typhus in India consists partly of the series of cases which have been described in the preceding article and partly of the cases which are reported in tabular form in the present note. In three of these cases there is a clear history of bite by a tick within the usual limits of the incubation period of a disease of the kind. The disease is practically identical in its epidemiological features and its clinical manifestations with the Rocky Mountain fever which has been proved to be tick-borne. In no case of presumed tick-typhus in India was there the slightest evidence of louse infection, although in most of the cases this possibility was closely investigated. Taking all the evidence into account it is easy to explain all the cases on the hypothesis of tick transmission, and no other hypothesis which has been suggested is supported by the facts.

The tick carrier is probably *Rhipicephalus sanguineus*, but it is not possible to make a dogmatic statement to this effect, as in no case has the tick which was found biting a patient been available for identification. The evidence which points to this tick is circumstantial and inconclusive. It is that while in one of the infected zones I found a tick which was attaching itself to my leg, this bore a general resemblance to the tick which conveyed the fever to me some years previously in the same place and it was identified as *Rhipicephalus sanguineus*. It is hoped that the attention which has now been drawn to the point will result in the preservation and identification of the responsible tick in some future cases of the disease.

The only other vector which is at all likely to be responsible is a mite, but there is not the slightest evidence of bite by a mite in any case, and besides the local necrosis with lymphadenitis and the pronounced lymphocytosis which are described in the mite-borne

Further cases of Tick-Typhus in India.

typhus-like fever were entirely absent in the cases reported.

The existence of a typhus-like fever in India conveyed by ticks is reasonably certain, and the accounts of fevers in Nigeria, South Africa and other parts of the world strongly suggest that a tick-borne typhus-like fever occurs in these places.

So far as my own observations go, I feel justified in the belief that the best working classification of the typhus group of fevers is into

- (1) Louse-Typhus.
- (2) Tick-Typhus.
- (3) Mite-Typhus.

There are cases in which the vector is not known: in most of these the clinical picture and the epidemiological features are sufficiently characteristic to justify a reasonably certain diagnosis, but when there is no evidence of the vector and the symptoms are not characteristic it may be necessary to use the term typhus-like fever of unknown vector.

The proposed classification has the merit of calling attention to the typhus-like nature of the fever and its eruption and to the epidemiological features. Although the classification must remain provisional until the knowledge of the fevers is more definite, it will be found to be helpful to the medical man in handling these cases. That such help is needed has been abundantly shown by the serious difficulties in which medical men have often been placed, as the diagnoses of smallpox, syphilis, measles and paratyphoid fever have been made in several cases with the result that grave embarrassment of both doctor and patient has occurred. Other diagnoses like aberrant dengue have been made, and though these have not caused any serious practical difficulties, it is decidedly unsatisfactory that the medical man should find himself in a position in which he is unable to make a diagnosis on which he can base a rational handling of his case. In one case which was seen by six medical men there were six different diagnoses and some of the doctors were harshly and unjustly accused of professional incompetence, although the others whose diagnoses were equally wrong escaped censure. It is impossible to form any idea of the frequency of cases of this disease in India; it is likely that many cases escape notice among children in the endemic areas, and that the majority of the adults in these areas are immune so that the disease is chiefly observed in newcomers from non-affected places. The animal reservoir is not known but hares or other rodents are the most likely.

The geographical distribution is not yet known; cases have been recorded chiefly from Bhim Tal and Sat Tal in the Kumaon hills at a height of 4,500 to 6,000 feet, in the warm

season and from the Central India plateau at heights of 1,500 to 2,000 feet, and from the Orissa forests at about the same height, in the cold season. Isolated cases have been reported from several other localities, so that the disease probably has a wide distribution in the forest and scrub areas of India.

The season of occurrence appears to be the winter in the less elevated regions and in the summer in the higher areas. Prevention is probably on the same lines as in the case of the Rocky Mountain fever, viz., avoidance of tick bite and care in searching for ticks on the body after exposure to possible bites. If the ticks are removed within an hour or two of fastening on the body infection is not likely to occur.

The mortality is low among healthy adults, but fatal cases have occurred and one of the cases personally observed by me was nearly fatal. What is needed is for medical men in India and elsewhere to realise the possibility of the occurrence of the disease and to make observations of the epidemiology and symptomatology or any cases which appear to belong to the disease group.

Brief Summary of the Clinical Features.

The features of the disease may be summarised briefly as follows:—

The patient has nearly always been exposed to the bite of ticks and in some cases the tick has actually been found fastened on the body. After an incubation period which is usually about a week, but which may be as long as three weeks the fever appears, either suddenly with shivering or gradually with step-like rise, usually reaching its maximum within three or four days. Head-ache, pains in the joints and limbs are usually noticed with the onset.

About the third to the fifth day the eruption appears, this at first is a rosy macular or papular rash, the spots being slightly raised in some cases. They disappear on pressure, they are first seen on the limbs and usually extend all over the body. They are rather profuse as a rule and after a few days they become dark red and sometimes petechial. The face, palms and soles are often affected but sometimes escape.

At the height of the fever there is often conjunctival injection and sometimes sore throat. The fever lasts from twelve to sixteen days in most cases, but may last as long as three weeks. The temperature usually falls by lysis. The temperature at first is continuous or remittent, it is usually remittent towards the end. The spleen and liver are often somewhat enlarged. The blood shows a moderate leucocytosis as a rule. The Widal and Weil-Felix reactions are negative in most cases and blood cultures are sterile. Staining after the rash persists in most cases for some weeks. Person-to-person infectivity does not occur, and the cases are usually single unless a number of persons are exposed to the same

conditions. The appearance of the rash and the temperature curves can be gathered more readily from the pictures and charts than from a description.

The symptoms vary a good deal but not more than in other exanthems.

Conclusion.

I believe that it is now reasonable to assert with some confidence that a tick-borne fever of the typhus group occurs in India and the use of the term "tick-typhus of India" or "tick-typhus" will be most appropriate as a provisional designation for the disease. The term "spotted fever of India" has been suggested with a view to indicating the relationship to the known disease which it most closely resembles, but the word "spotted" has been used of so many diseases that it does not convey any precise idea, whereas the term tick-typhus will be applicable to the disease in any part of the world.

NOTES ON CARBON TETRACHLORIDE AS AN ANTHELMINTIC.*

By ASA C. CHANDLER, Ph.D.,

and

A. K. MUKERJI, M.D.,

(Contribution from the Hookworm Research Laboratory
financed by Indian Jute Mills Association,
Calcutta School of Tropical Medicine).

ALTHOUGH the expulsion of human intestinal worms has been a subject of interest to the medical profession for many centuries, the matter is still one which has not been satisfactorily solved. The qualities to be sought in an anthelmintic are (1) safety for the patient; (2) effectiveness in expelling worms; (3) simplicity of administration on a large scale; (4) lack of unpleasantness in taking or in after effects; and (5) cheapness. No anthelmintic can be expected to reach perfection in any one of these attributes; the problem is, therefore, to find anthelmintics which combine the highest degree of perfection in each of them. Nor is it reasonable to expect that any one anthelmintic will prove effective for all kinds of worms. Even at the present time well-known biological supplies companies are putting on the market patented anthelmintics which are claimed to be effective against such widely different organisms as hookworms, ascaris, oxyuris, and tape-worms. From a zoological standpoint such a universal action would be highly improbable, and practical experience has shown that, up to the present time, no anthelmintic is effective in anything like an equal degree against different kinds of worms.

The treatment of hookworm infections has undergone a very interesting evolution in recent years, and more

advance has been made toward the goal of an ideal anthelmintic for hookworms than for any other common helminthic infection. Until 1880 extract of male fern was most commonly used for the expulsion of hookworms, with very indifferent success. In 1880 thymol was introduced and, with betanaphthol as an alternative, was the classical drug for treatment of ankylostomiasis until seven or eight years ago, when interest in oil of chenopodium was revived. This latter drug steadily gained in favour and by 1921 became almost universally the preferred drug for treatment of both hookworm and Ascaris infections. It is distinctly superior to thymol in every one of the qualifications enumerated above. At the present time thymol has been almost entirely discarded as a remedy for hookworm except by those who are still practising the medicine of five to ten years ago. In 1921 Hall discovered that carbon tetrachloride would remove practically 100 per cent. of hookworms in dogs, and was highly effective for related worms in other animals, and he recommended its trial for the expulsion of hookworms in human beings. Since that time hundreds of thousands of human cases have been treated with the drug in all parts of the world, and it is now accepted in most places as an alternative, if not a substitute, for oil of chenopodium. In the meantime much valuable work has been done on its physiological effects and we now know many of the factors which control its safety, and the precautions which must be taken in its use. It is timely, therefore, to compare the relative values of carbon tetrachloride and oil of chenopodium as regards the qualifications for an anthelmintic enumerated above.

Safety for the patient. No effective anthelmintic so far used has reached the perfection point as regards safety to the patient; all of them do a certain amount of temporary damage and, under certain conditions, may prove fatal. Most anthelmintics are highly poisonous if absorbed into the system, and their toxicity depends to a great extent on the degree to which absorption takes place. Thymol, in the absence of fats or alcohol, is highly insoluble and almost harmless, but in uncontrolled patients, particularly children, fatalities occasionally occur due to ingestion of these substances before the thymol has been eliminated. Oil of chenopodium in an ordinary therapeutic dose of 30 minims for an adult usually produces only slight symptoms of nausea, dizziness and gastro-intestinal irritation, or none at all, but in poorly nourished or fasting individuals, or in very young children, the toxic effects are greatly increased and may be fatal. There is, in fact, a long list of fatalities charged to the use of oil of chenopodium as an anthelmintic. According to McVail (1922) kala-azar patients do not stand chenopodium treatment well, and the drug is contra-indicated in the case of pregnant women (Lambert, 1923a). Since oil of chenopodium is not a simple chemical compound its composition varies, and also its toxicity.

Carbon tetrachloride (CCl₄), on the other hand, is a simple chemical compound, closely allied to chloroform and, therefore, of invariable chemical composition. It does, however, very commonly, in fact usually, contain impurities, the more common of which are carbon bisulphide and phosgene. It has been a

* Read before Indian Science Congress, January 1925.

common opinion that these impurities, even in very small amounts, add greatly to the toxicity of the drug, and that some of the fatalities recorded were due to their presence. Although the evidence for this is far from conclusive, it is important that until more is known about it all samples of CCl_4 for internal use should be analysed by a competent chemist. Major G. C. Boyd, I.M.S., suggests that the following standard of purity be demanded of CCl_4 put on the market for internal use:—

When ten c.c. of the sample are shaken with twenty c.c. of distilled water for five minutes and time allowed for the complete separation of the liquids the wash water employed;

(1) should be neutral to litmus;

(2) should show not more than a slight opalescence when treated with four drops of a solution of silver nitrate (5 gms. silver nitrate dissolved in 100 c.c. distilled water);

(3) should not give any colour with one c.c. of a solution of cadmium iodide (5 gms. cadmium iodide dissolved in 100 c.c. distilled water) and two drops of mucilage of starch.

Twenty-five c.c. of the sample when evaporated on the water bath should leave no residue.

After shaking twenty c.c. of the sample with ten c.c. of pure sulphuric acid for fifteen minutes both the acid and the carbon tetrachloride should be nearly colourless.

A well-cleaned small silver coin should show no darkening when immersed in the sample for ten minutes.

Newcomb's test for carbon disulphide should be negative. One c.c. of the sample is mixed with two c.c. of aniline oil and two drops of ammonia solution (0.0880). After standing five minutes two c.c. of a one per cent. solution (recently prepared) of sodium nitroprusside is added and the mixture shaken. A purple colour in the sodium nitroprusside layer indicates the presence of carbon disulphide. No positive reaction should be obtained with Schiff's reagent.

The benzidine test should be negative.

Very few of the samples submitted to us by chemical firms meet these requirements, but it is hoped that in the near future this condition will be improved.

CCl_4 is much less soluble in water than is chloroform, and even less so than thymol; it is therefore absorbed through the intestinal wall only in small amounts under ordinary circumstances. Recent work indicates that the condition of the patient as regards nutrition and diet has more to do with the toxicity of the drug than has the size of the dose. Under favourable conditions dogs can withstand doses up to stomach capacity (up to 25 c.c. per kilo), or over 80 times the therapeutic dose of 0.3 c.c. per kilo. Monkeys have been given up to 6 c.c. per kilo, which is over 100 times the therapeutic dose first recommended for man. Human doses exceeding 12 c.c. in a single dose (Leach 1922) and 36 c.c. in daily doses of 4 c.c. (Escobar 1922) have been given without apparent ill effect. On the other hand recent work (Schultz and Marx 1924) has shown that doses as low as 0.25 c.c. per kilo may damage the liver in dogs, whereas doses exceeding 1 c.c. per kilo invariably do so. Since it is likely

that the effects of the drug in man are similar to those in dogs, and since the equivalent of a human dose of 3 to 4 c.c. may produce definite hepatic lesions in these animals, there is reason to believe that these doses may also cause some liver damage in man. From this Schultz and Marx conclude that 3 c.c. is almost within the limits of safety but that this dose cannot be exceeded without courting serious damage to the liver, and that there is therefore no margin of safety. It has been pointed out, however, by Phelps and Hu (1924), Schultz and Marx and others that under ordinary circumstances a very high degree of hepatic necrosis, even up to 75 per cent., can be endured by an animal with only slight external evidence of injury, and that the damaged cells are repaired with almost spectacular rapidity; numerous mitotic figures at the edges of the necrotic area can be observed within 40 hours after the administration of the drug, and within a few days the damage is completely repaired. Bose and Mukerji (1924) performed the levulose tolerance test on 8 cases of uncomplicated ankylostomiasis treated with 70 min. CCl_4 in sat. mag. sulph. on two consecutive days, the test being performed from 1 to 18 days after the last dose of the drug. No evidence of disturbance of liver function was found in any of these cases. Schultz and Marx, however, call attention to the danger of necrotic tissue in affording a foothold for bacteria carried from the intestine by the portal veins, and state that infections of this type, usually of a low grade, exert a pronounced influence on the nature of the repair. In such cases marked fibrosis may occur, and they think that such lesions may conceivably go on to a true cirrhosis.

There is evidence, however, that the liver damage can be to a large extent controlled. The simultaneous or subsequent administration of magnesium sulphate affords some protection, and Davis (1924) has shown that the diet has a very pronounced effect. Starvation or a fat diet markedly increase the amount of liver damage, whereas a diet rich in carbohydrates, and to a less extent a protein diet, exerts a very decided protective influence. It is evident that a preliminary starvation period extending over more than a few hours, as is customary with many anthelmintics, is absolutely contra-indicated in the case of CCl_4 . Alcohol has been shown to increase the toxicity of the drug, and it is obvious that cirrhosis or other liver derangement, due to chronic alcoholism or any other cause is a contra-indication. CCl_4 can, however, be given with confidence, as McVail (1922) has pointed out, in cases of kala-azar and malaria during remissions of fever, whereas kala-azar patients stand chenopodium badly. In cases of pregnant women CCl_4 is well tolerated,

Lambert (1923a) reporting the treatment of some hundreds of cases without a single abortion.

The dosage employed for man varies in different hands from 3 c.c. to 10 c.c. or more in single doses. Escobar has given 4 c.c. daily for 9 days. The Philippine Health Service (Leach, 1924) has treated over 35,000 cases with an average dose of 7.5 c.c.; individual doses have ranged from 6.2 to 12.5 c.c. Lambert (1923) in Fiji has treated 60,000 cases with doses of 3 to 4 c.c. for adults, and 3 minims for each year of age up to 15 years; Docherty and Burgess (1922) in Ceylon gave 5 c.c.; Sawyer, Sweet and Shaw (1923) in Australia gave from 3 to 10 c.c.; and McVail in Calcutta gave 60 and later 70 minims on two consecutive days. The dose we now employ at the Calcutta School of Tropical Medicine is a single dose of 70 minims for an adult. The fatalities that have been reported from the use of CCl₄ have not been associated with the larger doses. Lambert had a fatal case in a boy of 5 with a dose of 1 c.c., another in a boy of 7 with a dose of 1.75 c.c., and Phelps and Hu had a fatal case in a boy of 5½ with 1 c.c. Most of the other fatal cases which have been reported have followed the administration of 3 c.c. in adults. Lambert's fatal cases occurred in individuals heavily infected with *Ascaris*, and after the administration of a sample of drug which was found to be far from pure.

To sum up we feel justified in concluding that a dose of from 3 to 5 c.c. (for an adult) of chemically pure CCl₄ is as safe or safer than oil of chenopodium or any other effective anthelmintic, providing the drug is accompanied or followed by a saline purge, and that the patient is well nourished and has a normal liver, refrains from the use of alcohol for a day or two before and after treatment, and is given a diet rich in carbohydrates and poor in fats. The fact that Lambert's fatal cases had heavy *Ascaris* infections suggests that such infection may possibly constitute a contra-indication.

Effectiveness. On the score of effectiveness it is almost universally agreed that a single treatment with from 3 to 5 c.c. of CCl₄ is more effective for *Necator* infections than is a single treatment with 1.5 c.c. of chenopodium, which is the maximum considered safe for routine field work. With oil of chenopodium, Hampton (1922) in Ceylon reports 30 per cent. to 50 per cent. of microscopical cures after 1.5 c.c. (as against 90 per cent. after 3 c.c. of CCl₄); Darling and Smillie (1921) in Brazil got only 14 per cent. of cures from one treatment with 1.5 c.c. (divided), and 41 per cent. from two treatments (divided doses); Caius and Mhaskar (1919) in Madras got 55 per cent. of cures after 32 minims

(divided), but their criterion of cure was the result of a subsequent dose of 60 grains of thymol; Destéfano and Vaccarezza (1924) in Argentina got 30 per cent. of cures (as against 60 per cent. with CCl₄); Cadbury (1924) in China got 58 per cent. of cures from 3 c.c. undivided (as against 36 per cent. with from 3 to 6 c.c. of CCl₄). Darling, Barber and Hacker (1920), however, claim that 1.5 c.c. of chenopodium in three divided doses will remove 99 per cent. of all worms present. This is considerably better than we have been able to do, although it is true that a very high percentage of the total worms present, exceeding 90 per cent., may be removed in spite of a comparatively low percentage of microscopical cures.

The percentage of microscopical cures is not as good an absolute criterion of the effectiveness of an anthelmintic as is an egg-count before and after treatment, but it is useful as a means of comparison, since it is our experience that the percentage of worms removed increases with the percentage of cures, though not necessarily in the same proportion. It is only under exceptional conditions that really reliable data on the percentage of worms removed can be obtained by worm counts. Of 41 cases treated with chenopodium at the Carmichael Hospital for Tropical Diseases in Calcutta by Dr. McVail and ourselves, 30 cases (73.2 per cent.) were definitely not cured by one treatment with 30 minims in divided doses, five cases (12.2 per cent.) were definitely cured, and 6 cases (14.6 per cent.) were doubtful cures in which at most only one or two female worms were left. It should be noted, however, that about one-fourth of these cases had previously resisted CCl₄ treatment and therefore only the more resistant worms remained. The varying results obtained by different workers is probably due in part to varying efficiency of samples of oil, and in part to method of administration, but principally, we think, to the criterion of cure. Our present criterion is a series of 5 or 6 negative examinations, beginning several days after treatment, by the Kofoid and Barber technique. We think it is safe to say that oil of chenopodium in one divided dose of 30 minims eliminates all the female worms in from 20 to 40 per cent. of cases only, whereas two treatments will cure from 50 to 60 per cent. of cases. The drug is less effective for *Ancylostoma* than for *Necator*, but the difference is not so marked as in the case of CCl₄. As regards CCl₄, the percentage of cures with initial doses is distinctly higher. In one series Nicholls and Hampton (1922) got 88 to 90 per cent. of cures in a single treatment, but cured only 2 of 4 children previously treated with chenopodium; Smillie and Pessoa (1923) got 98 per cent. of worms with one treatment; Lambert (1923a) got 94.5 to 99 per cent. of worms with one treatment, although

in one series of 14 cases in which 94.5 per cent. of worms were obtained only 50 per cent. were cured; and Cadbury (1924) in China got only 36.1 per cent. of cures. In a series of cases treated by us in the Alipore Central Jail with the kind co-operation of the Superintendent, Lieut. H. A. Young, I.M.D., we succeeded in curing 96 per cent. of 50 patients, 25 of whom were given 70 minims in mag. sulph., and 25 getting 70 minims in milk without subsequent purge. Only one in each series showed ova by the Kofoid and Barber technique 10 days after treatment. In the cases treated by Dr. McVail and ourselves in the Carmichael Hospital in Calcutta the results have not been so good, and varying results have been obtained according to the method of administration. The results of the various methods are summarized in Table I, in which not only the total percentage of cures and possible cures by first, second and subsequent treatments is given, but also an analysis of the results for pure *Necator*, pure *Ancylostoma*, and mixed infections, as well as cases in which worms were not recovered and the species, therefore, undetermined. The latter were probably all light, and presumably the majority of them *Necator* infections, which may account for the rather high percentage of cures in these cases. The cases grouped as doubtful cures are early cases in which the criterion of cure was not sufficiently rigid to make it sure that all the female worms were eliminated. It will be noted that in practically every instance the percentage of cures for ankylostome and mixed infections is markedly lower than for *Necator* infections. Sawyer, Sweet and Shaw in Australia got only 21.8 per cent. of cures of pure ankylostome infections with 3 c.c. of CCl_4 , and 30 per cent. with 5 c.c. There is little doubt but that Cadbury's small percentage of cures in Canton was due to a high percentage of cases harbouring ankylostomes, since Darling (1920) has shown that of infected Chinese in southern provinces over 80 per cent. harbour at least part ankylostomes, whereas according to Faust (1923) the percentage of ankylostomes is much greater in the central and northern parts of China. We have had one ankylostome case which was only doubtfully cured after three CCl_4 treatments, four chenopodium treatments, and two beta-naphthol treatments.

To summarize it may be said that a single treatment with from 3 to 5 c.c. of CCl_4 , accompanied or followed by a purge, will cure from 70 to 90 per cent. of *Necator* infections, and a much lower percentage, probably not over 30 to 40 per cent., of ankylostome infections. CCl_4 is, therefore, much more effective than chenopodium for *Necator* infections, and approximately on a par with it, or a little inferior, for ankylostome infections. So far

as is known *Necator* infections predominate in all parts of India.

Simplicity of administration. On the score of simplicity of administration on a large scale, CCl_4 is again distinctly superior to oil of chenopodium. The latter is most effective if given in 3 divided doses, and it must be followed by a saline purge, which means that each patient must be seen four times. With CCl_4 each patient need be seen only once, or at most twice, in case a subsequent saline purge is given. In mass treatments this factor is one of great importance. Furthermore, while chenopodium has to be carefully measured out into 3 capsules for each dose given, CCl_4 can be measured more roughly directly into the fluid to be used as a vehicle.

Unpleasantness and after effects. Hall and Shillinger (1924) state that patients who have previously taken chenopodium or thymol are unanimous in their preference for CCl_4 , and our experience corroborates this. Nearly all patients after taking CCl_4 feel a slight giddiness and often become drowsy, but they do not object to these symptoms. In many cases they are able to carry on the day's work as usual if no salts are taken. Giglioli (1924) reports the loss of only 58 hours of work out of a possible 2,150 hours after the treatment of 252 mine labourers in British Guiana. Nausea is rare and vomiting is less frequent than after chenopodium. In some cases patients become mildly delirious, and in a few instances a transient jaundice follows after one or two days. Chenopodium, on the other hand, is very disagreeable to take, frequently causes nausea and vomiting, and produces dizziness, intestinal irritation, and frequently headache. Alarming symptoms develop more frequently than after CCl_4 .

Cheapness. In cheapness CCl_4 has a decided advantage over oil of chenopodium. With CCl_4 at Rs. 2-8 per pound, the present price for a pure product in Calcutta, a dose of 70 minims works out at approximately $\frac{1}{2}$ anna, and if given in two ounces of milk the cost for a treatment comes to $\frac{3}{4}$ anna. Oil of chenopodium, on the other hand, at Rs. 32 per pound, comes to 2 annas for a 30 minim dose, plus about $\frac{1}{2}$ anna for 3 capsules, making $2\frac{1}{2}$ annas in all. The cost for chenopodium is still further increased if account is taken of the time required for measuring out the 10 minim quantities into capsules ready for dispensing.

Modes of administration of CCl_4 . It was first recommended by Hall that CCl_4 be administered in hard gelatine capsules. In practice, however, this method has only rarely been used, and the simpler method of administration in a fluid has generally been followed, and with as good results. Most workers, including Lambert and Leach who have reported on the treatment of 60,000 and 35,000 cases

respectively, have given it in water. In some instances, it is followed after two or three hours by a saline purge, although the drug itself has some cathartic action. McVail began giving the drug in water, with or without a subsequent dose of magnesium sulphate or jalap powder; later he tried the drug in castor oil, and still later in saturated magnesium sulphate solution as a vehicle; he gave the full dose of 60 to 70 minims in these ways on two consecutive days. Lambert (1923b) has reported on the treatment of 7,000 cases using magnesium sulphate as a vehicle with very good success. Hall and Shillinger (1924), experimenting on dogs, conclude that the action of the drug is not impaired by the simultaneous administration of salts.

Early in 1924 we began using milk as a vehicle, and think that this is the most satisfactory method of administering CCl₄. Hall and Shillinger (1923) report on a single test to determine the effect of CCl₄ when taken in milk, and found the effects more noticeable than in previous tests with capsules. Lamson et al. (1923) found that CCl₄ given an hour after heavy cream was greatly increased in toxicity. Apparently drawing conclusions from this, an editorial in the Journal of the American Medical Ass'n, 1924, states that "it appears more than doubtful whether milk should be used as a vehicle for carbon tetrachloride, as is sometimes recommended." Balfour (1924) repeats this statement. Hall and Shillinger are evidently under the impression that the CCl₄ should mix with the milk on account of its being a fat solvent, but find that the drug nevertheless settles to the bottom. With the assistance of Major A. D. Stewart, I.M.S., we studied the nature of a mixture of CCl₄ in whole milk, skimmed milk, and cream, both macroscopically and microscopically, and found that the drug could be emulsified in skimmed milk quite as readily as in whole milk, being held in a fine emulsion for some time by the colloidal protein particles. We vigorously shake the dose of CCl₄ with a few c.c. of milk in a test tube to get a fine emulsion, and then stir this into two or three ounces of milk. The CCl₄ slowly settles out in the form of larger globules, but this is not sufficient to be evident to the eye for ten or fifteen minutes. In our hospital work we use the natural milk, in which the fat content runs from 4 to 6 per cent. and have had no trouble from it, but for general use we recommend skimmed milk as being equally useful as a vehicle, less dangerous, and cheaper.

We can find no evidence that CCl₄ given in milk produces more symptoms than when given in water or magnesium sulphate. To test this we simultaneously treated 25 prisoners in the Alipore Central Jail with CCl₄ in salts and 25 with CCl₄ in milk without subsequent purge. Nine (36 per cent.) in each

group vomited, but repeated vomiting occurred more frequently in the mag. sulph. group; symptoms of mild intoxication or of abdominal pain occurred in six (24 per cent.) in each group; slight giddiness was remarked by every individual in both groups; a severe jaundice developed in one individual, suffering from tuberculosis, in the magnesium sulphate group. A single examination made ten days later by the Kofoed and Barber technique showed all but one in each group to be negative. The purging was, of course, more marked in the magnesium sulphate group. In our hospital cases the amount of vomiting and intoxication seems to be about the same regardless of the vehicle, but the CCl₄ is less objectionable in milk than in either water or salts. If followed by a saline purge two hours later CCl₄ in milk produces a very high percentage of cures in one treatment, especially in Necator infections (see Table I). It is probable that the emulsification in milk brings about a more even and thorough distribution in the intestine.

Dr. McVail at the School of Tropical Medicine, assisted by one of us (A. K. M.) tried combinations of CCl₄ and oil of chenopodium on a series of 22 cases, the usual dosage being 45 to 60 minims of CCl₄ in water accompanied by 10 to 15 minims of chenopodium in a capsule. Fifty per cent. of these cases were cured in a single treatment, and 4 of 7 (57 per cent.) who were given a second treatment were cured. These results compare very favourably with any other methods of treatment we have tried, and they warrant further trial especially in places where Ascaris infections are common. (Lambert (1923a) reports favourably on the treatment of several hundred cases with a mixture of 1 part of chenopodium to 11 of CCl₄, the latter being used in the usual dosage. Sawyer and Sweet (1924), however, in a series of patients having a high preponderance of Ancylostoma, got poorer results from a combination of CCl₄ and chenopodium than from either one alone.

From Table I, which summarizes the results obtained by Dr. McVail and ourselves at the Carmichael Hospital, certain conclusions as regards the method of administration of CCl₄ can be drawn. It is clear that CCl₄ repeated on two successive days, other things being equal, is more effective than a single dose, but since the damage to the liver reaches its maximum about 48 hours after the administration of the drug the second dose takes effect at a dangerous time, and we think that the possibility of serious results is greatly increased by a repetition of the drug in less than 7 or 8 days. Castor oil as a vehicle does not increase the efficiency of the drug, and may be considered dangerous in that more absorption may be expected. Magnesium sulphate as a vehicle or as a subsequent purge does not

N=Pure Necator; A=Pure Ancylostoma; M=Mixed infections; ?=Species undetermined.

reduce the efficiency of the drug, and it is known to reduce its toxicity. Milk as a vehicle, if followed by a saline purge, is as effective as any method of administration we have tried, and is least objectionable. A combination of CCl₄ and chenopodium is very effective and deserves further trial.

CCl₄ in the treatment of other intestinal worms. CCl₄ is generally considered to be less valuable in the treatment of *Ascaris* than of hookworm infections, both in dogs and man. Chopra and McVail (1923) found that the drug had little action on *Ascaris in vitro* and conclude that it is not likely to be of much use clinically. Leach (1924) succeeded in curing only 9.4 per cent. of 53 cases. However, of 25 cases treated at the Carmichael Hospital 11 (44 per cent.) were cured by a single treatment of two doses of CCl₄ on successive days, mostly in castor oil or magnesium sulphate. Of 6 cases given a second treatment 3 were cured. With oil of chenopodium we have had 56.7 per cent. of cures and with santonin 75 per cent. (Chopra and Chandler, 1924). A single dose of CCl₄ in milk followed by magnesium sulphate was less effective, only 1 of 5 cases being cured. CCl₄ accompanied by chenopodium was highly effective in the few cases in which it was tried, 5 out of 6 cases becoming negative after one dose. Four of six cases which were not cured by CCl₄ subsequently became negative after one treatment with chenopodium, whereas in one instance four subsequent treatments with chenopodium were necessary to effect a cure.

In the case of *Oxyuris* also CCl₄ has a very decided action. No definite comparisons can be drawn because it is impossible to determine a cure by microscopical methods, and reinfections occur so commonly that a subsequent presence of worms is little indication that all the worms present at the time the drug was given were not eliminated. We can only say that the number of worms eliminated after oral administration of CCl₄ is as great or greater than with any other anthelmintics we have tried. In 6 of 16 cases given subsequent treatments with CCl₄, chenopodium, or other anthelmintics no more worms were passed, and in each of 3 more cases given 3 or 4 subsequent treatments only one more worm was passed; in only 5 of the 16 were more worms passed on subsequent treatments than on the first. In one case 1,314 *Oxyuris* were passed after the first CCl₄ treatment, and over 250 after the second. We have also experimented with enemata consisting of 6 c.c. of CCl₄ emulsified in 6 ounces of warm milk (adult dose). The patient is given a strong dose of salts the night before treatment and is treated in the morning after his bowels have emptied. The foot of the bed is raised about a foot and with the patient lying on the right side the milk is slowly injected as far into the colon as possible. The enema is not irritating and the patient can usually hold it easily for two hours, after which he is asked to expel it. The *Oxyuris* which are passed are all dead and those passed on the next day are in a state of partial disintegration. We treated 7 cases which had

passed one or more Oxyuris after CCl_4 by mouth, but 5 of these failed to pass any more worms after this or subsequent treatments. One case which had passed a total of 8 worms after 3 previous treatments, two with CCl_4 and one with chenopodium, passed 5 worms. Another case which had passed only one Oxyuris after oral CCl_4 , passed 15 females and 11 males. Two other cases which were passing Oxyuris in the stools but had had no previous anthelmintic treatment were each given a series of 3 rectal injections at intervals of 3 days. One passed 24, 3 and 2 worms and the other 26, 165, and 24 worms respectively after the 1st, 2nd and 3rd injections. While these data are insufficient to warrant any definite conclusion as to the value of the treatment, they are at least promising. It is suggested that in severe Oxyuris cases a carefully administered enema of CCl_4 in milk, to be retained for two hours but not longer, together with the usual oral dose given simultaneously, followed by salts in two hours, might produce very good results. It is, of course, necessary in any Oxyuris treatment that precautions be taken against reinfection. Eight of the nine patients, who were given the rectal injection in a dosage of 6 c.c., complained of no symptoms, whereas one who was given 8 c.c. complained of giddiness for several hours after. Lamson et al. (1923) have shown that absorption of CCl_4 takes place in the large intestine after large rectal injections and that some liver damage results. When diluted in milk, however, and only retained for two hours, it is likely that very little absorption takes place, and a dose of 6 c.c. can be injected with confidence in patients of 12 years or more if well nourished and in good health.

Out of well over a hundred cases harbouring Trichuris only two or three have passed any of these worms after CCl_4 treatment, and none has been cured of the infection. The drug also has little or no action on Strongyloides, or on tapeworms, either Tænia or Hymenolepis. Its anthelmintic action, therefore, so far as the common human intestinal worms are concerned, is limited to hookworm, ascaris and oxyuris.

SUMMARY.

1. An anthelmintic should be judged on the basis of (i) safety for the patient; (ii) effectiveness in expelling worms; (iii) simplicity of administration on a large scale; (iv) lack of unpleasantness in taking or in after effects; and (v) cheapness. No one anthelmintic can be expected to be effective for all kinds of worms.

2. As regards safety to the patient, CCl_4 in a dose of from 3 to 5 c.c. can be regarded as being as safe as any effective anthelmintic, and distinctly safer than oil of chenopodium,

providing certain precautions be taken. The drug should come up to a certain standard of purity; it should be accompanied or followed by a saline purge; it is contra-indicated in badly under-nourished or very weak individuals; fats and alcohol should be avoided when it is used; cirrhosis or other liver derangement is a contra-indication; and a diet rich in carbohydrates and poor in fats is indicated. It can be given with confidence to kala-azar and malaria patients during remissions of fever, is well tolerated by young children, and is safe for pregnant women. In these latter respects chenopodium is distinctly inferior.

3. In effectiveness CCl_4 is distinctly superior to chenopodium in eliminating Necators, whereas it is approximately on a par or a little inferior in removing ankylostomes.

4. In simplicity of administration on a large scale CCl_4 has a distinct advantage in the number of times it is necessary to see each patient, and in that capsules are not required.

5. A single treatment with CCl_4 costs from $\frac{1}{2}$ to $\frac{3}{4}$ anna, whereas a single treatment with chenopodium costs $2\frac{1}{2}$ annas, plus the cost of filling capsules.

6. CCl_4 has been administered in capsules, or in water, castor oil, magnesium sulphate, or milk as a vehicle, with or without a subsequent saline purge. We recommend a 70 minim dose in skimmed milk followed by a saline purge. A combination of CCl_4 and chenopodium is also very effective, and especially valuable where ascaris infections are common.

7. CCl_4 has a distinct ascaricidal action, especially when combined with chenopodium. Alone it is a little less effective than either chenopodium or santonin. CCl_4 given orally seems to have a more decided action on oxyuris than any other anthelmintic we have tried. Promising results have been obtained in a few cases from rectal injections of the drug in warm milk. This combined with a dose by mouth is worthy of more extensive trial. The drug has little or no action against Trichuris, Strongyloides, or tapeworms.

LIEUT.-COLONEL, I.M.S.,

Director, Bombay Bacteriological Laboratory, Parel,
Bombay.

THE village of Dhagur, 9 miles N. W. of Nasik, was inhabited until recently by a population of about 400, living in some 80 houses, Mahrattas in the centre, with Kolis and Chamars on the outskirts. It was well situated on sloping ground, well drained and exposed to the west. Water supply was from a *nala* about half a mile away down the slope.

It is now deserted and the former inhabitants live in two villages, $\frac{1}{2}$ to 1 mile away. The older inhabitants state that the migration is solely due to a disease which has in recent years carried off a considerable number of their young males, a disease they dread; which has earned for the village the name of *potedhagur* (*pote* = big stomach). This disease, they state, is always fatal after a number of years, beginning at an early age and attacking only the Mahrattas. They are well acquainted with malaria, which also attacks them, but does not spare either sex or any age or caste. The disease they speak of begins in infancy or early life with abdominal enlargement associated with a large lump in the left side. There is a low type of fever and progressive weakness, and death always results in early adult life.

I am informed by Dr. J. Munsiff, Assistant Director of Public Health, that there is no kala-azar in this district, and the case to be

detailed was certainly not an example of that disease.

A table shewing the distribution of 12 cases of the disease in 3 families is appended. Other cases are spoken of, but are not so clearly known to the villagers who were interviewed. The Kolis and Chamars have always lived in

moderate development; face puffy, conjunctivæ moderately anæmic, tongue clean; appetite not good and digestion poor; lungs healthy; heart normal except for a hæmic murmur. *Abdomen* markedly prominent, especially in the upper half, with bulging of the lower ribs and visible enlargement of the liver and spleen. The usual round scars from branding over the spleen, some not quite healed. A moderate degree of ascites present.

Case	1	contracted disease at	15	and died at about	35.
"	2	"	"	"	6 " living, operation case.
"	3	"	"	"	1 " died at about 14.
"	4	"	"	"	12 " " " 30.
"	5	"	"	"	2 " " " 13.
"	6	"	"	"	2 " " " 9.

the village with them, but have not suffered from the disease. Marriages in the Mahratta families have been with people of other villages.

No fresh cases have yet occurred in the new villages.

Shankar Kondaji is the only case seen personally, as there is at present no other case living. It is stated that all the previous cases have exactly resembled his, but it must be added that occasional cases from other villages of severe ascites in young males associated with cirrhosis of the liver or kidneys have been treated in the hospital.

Shankar Kondaji, aged 16, came to the Civil Hospital, Nasik, on 21-7-1924, for abdominal tumour and weakness. These symptoms began at about the age of 6, shortly followed by a low type of fever without rigors. Fever has been more or less continuous and the weakness and abdominal distension are increasing, but he has had practically no pain. He is very much afraid of the disease as his father and brother both died of it, the latter during the present year. He asked for the tumour to be removed by operation.

Physical examination; a boy of short stature and

The spleen forms a large tumour, occupying the majority of the left and upper diagonal half of the abdomen. Its lower end reaches to the left iliac fossa and its anterior border crosses the middle line just above the umbilicus. Its consistence is hard and it is movable only within small limits.

The liver is also greatly enlarged and its lower edge extends 3 finger breadths below the costal margin, which is much more horizontal than usual.

The other abdominal viscera are normal, there is no oedema, the urine is normal, and there is no palpable enlargement of any other lymphatic tissue.

In hospital there was no fever. Blood films shewed no malarial parasites and no leukæmia; differential count approximately as found later by Colonel Mackie. The Wassermann reaction was negative. The aldehyde test for kala-azar was negative, which, with a history of such length, almost certainly excludes kala-azar, and as the serum in addition remained fluid for 48 hours after addition of the formalin, malarial cachexia can (in the writer's experience) be also excluded.

The patient was given a potassium iodide mixture, ung. hydr. rubr. over the spleen and 3 doses of 3 grains of atoxyl hypodermically. He shewed no improvement, in fact he seemed to be slowly getting weaker. He daily asked for splenectomy, and as the disease had now been diagnosed as Banti's disease, his request appeared to me to be sound. Colonel Mackie, who

happened to be in Nasik, very kindly saw the case with me and also considered that the operation was justifiable as offering the only chance of saving the boy's life.

Operation, 1st September. Under chloroform, the abdomen was opened by a median incision 7 inches long, beginning just below the ensiform cartilage. Later the upper end of this incision was carried outwards about 3 inches towards the 9th left costal cartilage to enable the diaphragmatic adhesions of the spleen to be dealt with. The splenic pedicle gave much trouble, being greatly thickened and complicated with adhesions. Its veins were very large and tortuous and tore under the least strain, so that several times the most formidable hæmorrhage had to be stopped in the depths of the wound by using the extended fingers of the left hand as clamps until large clamps could be applied behind the fingers. Adhesions bound down the spleen to the lateral abdominal wall, to the intestines and to the diaphragm, the latter being strong and giving trouble on account of their depth in the wound. These adhesions having been divided, the spleen was freed laterally and turned forwards so that the deepest part of its pedicle and the gastro-splenic and lienorenal ligaments could be ligatured and cut. Finally the tail of the pancreas was separated and the spleen removed. It weighed 3 lbs. 3 ozs. The abdomen was cleaned of blood clot, filled with hot saline and closed.

The patient remained critically ill until the 3rd, with restlessness and increasing distension. The latter was relieved with 4-hourly injections of pituitrin combined with eserine. On the 3rd he was somewhat better, but on the 4th his temperature went to 104.8° with rapid respiration and signs of congestion at the left base. Trouble at the base was not surprising considering the dense adhesions separated just below the diaphragm here. However, he did well and by the 7th his condition was excellent.

As his general condition improved, the shape of the lower ribs became more normal, but the liver remained much enlarged below the costal margin. The patient became less anæmic and the digestion much better. The liver must have undergone reduction, as the ribs over it came down better.

He left hospital on the 22nd September, three weeks after the operation, and immediately resumed light work in the fields near his village. He was seen again on 26th October in good health and able to be out at work all day. His liver was still palpable but smaller.

I am greatly indebted to Colonel Mackie for his interest in the case and for the pathological notes given below. Also to my surgical assistant, Mr. Sheikh, for enquiries at the village and for much practical help.

REMARKS ON THE PATHOLOGY OF THE DISEASE.

By F. P. MACKIE,

LIEUT.-COLONEL, I.M.S.

As I happened to be in Nasik at the time, I was privileged to see this interesting case and it reminded me of a series of similar cases I saw when last in Nasik in 1907. On that occasion the diagnosis was similarly in doubt and I remember assisting the Civil Surgeon (then Capt. Novis, I.M.S.) to remove the spleens of two cases. We encountered the same difficulties in the operation which Capt. Spackman describes, and, as with his case, the immediate results were successful.

These splenomegalies are common in India, and though the majority can be attributed to

malaria or kala-azar, there are other types which cannot be attributed to these diseases. I have encountered such cases in all parts of India, cases characterised by progressive enlargement of the liver and spleen with moderate and varying degrees of anæmia, terminating with dropsy of the extremities and ascites. Such cases have been searched for malarial and Leishmania infection without success and their causation is quite obscure.

Megaw has suggested that some of these are due to chronic formative peritonitis resulting from repeated attacks of dysentery, and though this may explain some cases, which show chronic fibrosis of the capsules of the spleen and liver with recurrent ascites, it does not account for the class of case such as we are considering in which there is progressive enlargement of the spleen and liver and which show no evidence of chronic peritonitis.

I used to think that these cases were similar to those of Egyptian splenomegaly, the causation of which has been for so long a puzzle, but it appears from recent literature that the Egyptian disease is due to chronic hyperplasia and fibrosis due to schistosome infections. From the work which Dr. Fairley and I have been recently doing on the *Schistosoma* infection of Indian goats it is certain that the brunt of the irritation brought about by ova deposition is borne by the liver, and the splenic hyperplasia is secondary and due to the interference with the portal circulation in the liver.

Schistosome infections of man are not known in India and it is improbable that this form of splenomegaly is brought about by such parasites.

Of the other types of splenomegaly, there remain to be considered those described by Gaucher, Banti, Von Jaksch, Hayem-Widal and the Chauffard-Minkowski syndrome which all have some points in common and the differential diagnosis of which is extremely difficult. Some of these, particularly the last named, have a marked familial incidence. This feature has been well brought out by Spackman's case and other points in the history point suggestively to some kind of transmissible infection.

No opportunity was afforded in this case of doing a blood count nor the detailed pathological investigation which one would have liked to do, but it is certain that there was no marked anæmia and the blood picture did not suggest any disease of the blood-forming organs.

The leucocyte count was as follows:—

Polynuclears	..	59 per cent.
Lymphocytes	..	30 "
Large mononuclears	..	8 "
Eosinophiles	..	3 "

The red cells were normal, and no abnormal cells were noted.

The sections of the spleen showed moderate thickening of the capsule but no increase in the fibrous trabeculae. The Malpighian corpuscles were decidedly reduced in number and some were undergoing a hyaline change. The general appearance under the low power suggested an alveolar arrangement of the splenic parenchyma and great reduction in the lymphoid tissue. The alveoli were seen to contain numbers of large polyhedral cells of endothelial type with large circular feebly-staining nuclei.

No Leishmania or other parasites could be seen and the general structure was light and open and not at all resembling the dense hyperplasia and fibrosis usually seen in protozoal diseases. These characters in general and the overgrowth of endothelial cells in particular decided one in regarding the disease as that of Gaucher's type of splenomegaly.

A Mirror of Hospital Practice.

A CASE OF CONTRACTURE OF THE MOUTH.

By N. S. NARASIMHAN, L.M.P. (Madras),
L.C.P.S. (Bombay),

Surgical Registrar, Government Rayapuram Hospital, Madras.

In the *Indian Medical Gazette* for last August a case is recorded by Dr. Holland of gangosa in Baluchistan, illustrated by a photograph. The following are particulars of a case which somewhat resembled the case illustrated in that photograph.

Alamelnammal, a Hindu female, aged 25, was admitted to this hospital on the 18th December, 1922, into the venereal section with ulcers on both lips of the mouth of three years' duration, and ulcers on the labia and vagina of six years' duration. She was very emaciated and anæmic. The lower lip was raised here and there above the surrounding tissues; the rest of the ulceration hard to the touch; in the genitalia the ulceration extended completely around the vagina and involved the whole of the labia and extended back as far as the anus. The ulcers looked very red and inflamed, with areas of slough intervening in places.

Dr. M. A. Khalique treated the case as one of infective granuloma by intravenous injections of tartar emetic. The Wassermann test was at first negative; no other blood examina-

tions were made or local scrapings taken. The local conditions in the mouth and genitalia improved, but the patient's lips became adherent and the mouth rapidly contracted.

The patient was taken over by Rai Sahib D. S. M. Trasi, M.B., for plastic operation. There were some nodules at the lips and it was feared that the operation would might break down. The Wassermann test on the 4th April, 1923, was now reported to be moderately positive; but further injections of antimony were given. The patient's mouth became so much reduced in size that it would only admit a rubber catheter, and for a long time she had to be fed through a catheter. Unfortunately no photograph was taken.

This case differed in several respects from that reported by Dr. Holland. There was no depressed scar below the circular orifice of the mouth, and no radiating scar tissue. The alæ of the nose were not affected.

Operation.—The patient was operated on by Rai Sahib Dr. S. M. Trasi under chloroform anaesthesia on the 2nd July, 1923. Flaps were cut and the skin flap stitched to the mucous membrane of the upper lip, and the mucous membrane flap brought out and stitched to the skin of the lower lip. The operation was a success, and the patient had a re-formed mouth. The patient has been subsequently seen by me from time to time; no change has taken place, the mouth is satisfactory, and there has been no recurrence of the granuloma.

The following points are of interest in the case:—The patient is a native of Madras, and although cases of yaws are occasionally encountered in Madras, the disease does not appear to have been yaws. Infective granuloma is very common in Madras in both sexes; it has been met with in such uncommon situations as the feet and face, although most commonly in the pudenda and groin. Infective granuloma in the genitalia does not lead to destructive changes in the deeper tissue, and among the cases which I have seen no dense scar tissue is left to lead to irregular and unsightly contracture. Recurrences are common, and I have known a patient who has not been benefited even after five years of continuous treatment with injections, x-rays and excision.

Is it possible that the mouth lesions and those in the genitalia were of different origin in this case? The response to antimony treatment is a feature of interest in the case. The ulcers in no way resembled those of yaws. Although the Wassermann reaction was positive at the second test, no anti-frambæsia or anti-syphilitic treatment was given. The case does not appear to have been one of true gangosa, but one simulating that condition.

Indian Medical Gazette.

FEBRUARY.

RECENT WORK ON THE DIAGNOSIS AND TREATMENT OF TROPICAL DISEASES.

It is impossible to review the year's work on tropical diseases in a brief note; most of the progress of the year has been of a gradual kind but very important advances have been made.

Malaria.—In malaria diagnosis has been made more accurate by the wider adoption of the thick film method and by the more general realisation of the need for repeated blood examinations in early cases of suspected malignant tertian infection. In such cases many disasters have happened in the past because a single negative blood examination has been accepted as excluding malaria. In treatment, the trend of opinion is to rely more on the well tried and safe method of administration of quinine or other cinchona alkaloids by the mouth; this has fallen into undeserved disrepute in the past because enough attention has not been paid to the frequent failures on the part of the patient and dispenser to ensure the actual administration of the doses which have been ordered. When care is taken to avoid the fallacy that it is enough to write a prescription and leave the rest to the mercy of unwilling patients and dishonest compounders there is rarely cause to complain of the results. This point has been repeatedly stressed by some Indian workers, but too often those who have little experience of the pitfalls connected with quinine administration still fall into error. Probably the same fallacy holds with regard to quinine as a preventive, it is impossible otherwise to explain the incredible differences which occur in the recorded experiences of various observers. The use of deliberately produced inoculations of benign tertian malaria in the treatment of general paralysis of the insane has emphasised a point of great importance; viz., that recently acquired infections are probably very much easier to cure than relapsing cases. Malaria would appear to behave in the same way as syphilis and amoebiasis in this respect, and it is likely that the treatment of the future will differ very much according to the duration of the disease. There will not be one standard treatment for the disease but several, and it is likely that the treatment of recent infections will be shorter than the existing standard of two or three months, while the treatment of old relapsing cases will probably take the form of several short courses with periods of intermission of the drug. No final opinion can yet be expressed on the relative values of the various alkaloids of cinchona, but stress is being laid on the necessity for bringing the reaction of the blood to the optimum condition by the administration of alkalies. In this

connection we believe that it is a mistake to withhold quinine in serious cases until the bowels and the blood have been attended to: the first dose should be given at once and the alkaline and purgative treatment can be started at the same time. By doing so there will be no waste of valuable time before making the attack on the parasite.

The intramuscular use of the cinchona alkaloids is unreservedly condemned by some, while by others it is regarded as the best method. Our view is that in cases of persistent vomiting or of failure to absorb the drug by the alimentary canal it may be necessary to give one or two doses by the muscle and to run the slight risk of local necrosis, but such cases are very exceptional. Intramuscular injections must be given with a full sense of responsibility and should be confined to the cases in which they are considered to be the lesser of two evils. Intravenous administration should also be regarded as an exceptional procedure and should be reserved for the cases in which instant action is essential. We do not yet know the best way of treating malaria, but we have reached a stage at which malaria can be treated more safely and effectively than any other of the great diseases.

Kala-Azar.—Kala-azar can now be diagnosed more certainly than formerly and at an earlier stage. Blood culture in the hands of experts is being used much more widely than formerly; unfortunately, the technique is difficult and few are in a position to adopt this method, so that the barbarous spleen and liver puncture have still to be employed by many. The cases in which these are required are now fewer because the simple aldehyde test has proved so reliable in long-standing cases that they can be excluded, while blood culture appears to be suitable for the earliest cases.

Difficulty in diagnosis is experienced especially in the cases of splenic enlargement which resemble kala-azar but which are due to the so-called splenic anæmia. These cases are often treated by a course of antimony, naturally without benefit. Cases of syphilitic fever with enlargement of the spleen are often indistinguishable from kala-azar apart from serum tests and effective blood culture tests, and there are other conditions in which chronic fever with enlarged spleen give rise to difficulties of diagnosis.

The treatment of kala-azar has reached an interesting stage. The newer forms of antimony like urea stibamine and Von Heyden's 471 appear to be effective in many cases which are refractory to the older drugs. Whether the efficacy of these drugs is partly due to the fact that large quantities of antimony are introduced into the body in a short time remains to be seen, but for general use neither of these drugs is available in sufficient quantity and at reasonable prices. When they are on the market at cheap rates it will be possible to estimate their value by wider trials. There is an unfortunate tendency to use the word "cure" too optimistically in connection

with kala-azar. Even scientific workers sometimes consider that a single negative blood or spleen culture at the end of a course of treatment is a guarantee of cure. The experience of Ehrlich in the early days of salvarsan ought to be a warning in this matter, and we hope that the results of a long series of consecutive cases which have been kept under observation for prolonged periods will soon be available, so that we can judge of the permanency of the cures which result from short intensive courses of treatment. There is already good reason to believe that the new drugs constitute powerful additional weapons in the struggle against the disease. The advances which have been made in the investigation of the method of spread of infection will be dealt with elsewhere; in this respect the outlook is decidedly promising.

Amœbiasis.—The treatment of amœbic dysentery has not crystallised to the same extent as that of malaria. Emetine is still the most popular drug, its action on the vegetative forms of the parasite is comparable with that of quinine in malaria. It is in the chronic cases that real differences of opinion are found. The future must decide whether repeated courses of emetine with long intervals of rest for the elimination of the drug, or the use of some of the newer remedies like yatren and stovarsol form the best treatment of these cases. The present tendency is to avoid drastic courses of treatment by unpleasant and irritant drugs like emetine bismuth iodide which were in fashion some years ago. It is believed by some that the cures which resulted in some cases from these were due to the violent irritation of the bowel rather than to the superior efficacy of the drug as an amœbicide. There are so many cases of chronic carrier infection with the parasite of amœbic dysentery but without symptoms that it is doubtful whether it is desirable to subject all of these to a long and drastic treatment. Possibly the best method will be to give them short courses of treatment at intervals and to keep them under observation for a long period. The carriers who have no symptoms should be instructed to regulate their diet and manner of life, especially in the matter of alcoholic indulgence. They are probably more liable to acute attacks of dysentery than the rest of the community and from their ranks many cases of hepatitis and liver abscess are drawn. They are also important as sources of infection, and it is essential that further work should be done to determine the significance of the carrier condition both to the individual and to the community.

Stovarsol has been found to give excellent results in a few cases in the temporary freeing of carriers from their cysts; it is too soon to say that these results will turn out to be uniform or permanent; should they be confirmed in a large series of cases the drug will be of great value as it is easy to take and does not interfere with the ordinary routine of life. More attention is

being paid to the possibility of secondary infections with other organisms in chronic amœbic cases, possibly the value of stovarsol and the other arsenicals will be found to be especially great in cases with secondary spirochaetal infections. Yatren may also owe some of its value to its influence on secondary bacterial infections.

Emetine periodide has not been widely tested; it is well worth further trial, but much work has still to be done before we can dogmatise on the difficult subject of the treatment of chronic amœbiasis of the bowel.

Dengue.—The causal organism of dengue has yet to be discovered, the spirochaetes which have been reported by certain workers cannot yet be accepted, and even if their existence were admitted there is reason to doubt whether the disease in which they occurred was really dengue. The charts which were published indicate that the disease is one in which the second rise of temperature occurs about ten days after the first onset, whereas in typical dengue the second rise occurs about five days after the onset. For this reason it seems likely that the disease was not dengue but a disease closely related to infective jaundice. It further resembles that disease in the occurrence of jaundice in some of the cases. The clinical distinction between dengue and sandfly fever is just as difficult as ever, many of the cases cannot be differentiated on clinical grounds, and in such cases it is only when there is reasonable certainty as to the insect vector that the differential diagnosis can be made. For this reason we adhere to the view that it is better to class the two diseases in one group and to use the names "sandfly dengue" and "mosquito dengue" when the vector is known. When the vector is not known the term "fever of the dengue group" is the only one which can reasonably be applied. Even in the case of yellow fever there are several workers who deny that Noguchi has established the causal relationship between the spirochaete and the disease, but this is a point on which workers in India cannot express an opinion.

Attention may again be called to the existing confusion between the Japanese seven-day fever and the seven-day form of dengue which was described by Rogers. At least two of the most popular text-books fall into the error of confusing these diseases, one of which is a form of dengue while the other is related to infective jaundice.

Leprosy.—Leprosy has definitely been removed from the class of incurable and untreatable diseases. The results of early treatment by modern methods are fully equal to those obtained in early tuberculosis, and there are good reasons for the belief that a well thought out plan for early treatment, combined with segregation of the more infective victims and educational propaganda, will enable India to deal effectively with the scourge. It would seem that the dawn of hope has already appeared, thanks to the persistent efforts of Sir Leonard Rogers and his devoted band of followers.

Plague.—This disease is likely to fade into insignificance during the next decade or two, though recrudescences of its activity may be expected on such a scale that further strenuous efforts are still needed for its control. The elimination of rats is one of the most promising lines of effort. Here we are not dealing with a risky or expensive experiment but with a procedure which will pay, apart altogether from its influence on the incidence of plague. It is becoming more and more evident that the rat population is proportional to the food supply which is available for these animals; we have only to eliminate the wasteful feeding of rats and plague will automatically come to an end. Inoculation and evacuation still have important places in the campaign when the disease appears, but they will rarely be needed if the rat population is kept under strict control.

Relapsing Fever.—This disease is much more important and much more widely spread in India than had been realised a few years ago. The disease must be suspected and looked for, otherwise it will continue its ravages. When the disease is detected the means of control are exceedingly simple provided that the persons who are affected agree to co-operate.

Typhus.—Typhus fever is a minor problem in most places in India but it is likely that many parts of the country are affected by a tick borne disease of the typhus group. This is related to the spotted fever of the Rocky Mountains and may possibly be identical with that disease. It has been discovered to exist in many of the jungle or semi-jungle tracts of India, but its presence is only detected when persons enter these areas from outside. The tick now comes into prominence in India as a probable vector of disease from jungle animals to man, and the name tick typhus will probably come into use.

Cholera.—The continued existence of this disease is a disgrace to India. Every civilised country of the world has freed itself from the cholera menace; if a determined effort were made in India the same result would be obtained. Inoculation has proved itself to be a most valuable means of controlling the disease; this is impracticable under present conditions in most places in India, and there is good reason to press on with the investigation of the value of oral vaccines which have been claimed to be effective in other parts of the world. There is much difference of opinion as to their value, but it is necessary that the method should be tested under conditions which will enable us to form a definite opinion as to its value and efficacy. The prophylactic use of essential oils has been so favourably reported on by some workers in India that it ought to be given an extended trial. This method—like oral vaccination—has the great advantages of simplicity and harmlessness. The real solution of the cholera problem consists in the detection, isolation and complete cure of the infected persons, including the carriers.

Bacillary Dysentery.—This disease is coming to be regarded as an infection which is almost universal throughout most places in India; children in this country are probably attacked at an early age, some degree of immunity results from these attacks, but this does not afford complete protection, so that when any individual has his resistance lowered by disease of other cause he is liable to a severe form of the disease. Also when persons are crowded together under conditions in which intense and virulent infection is likely to occur there may be epidemics in spite of the existence of a relative immunity.

Recent work goes to show that prisoners in jails can be protected by isolation of all who show naked eye indications of the disease on stool inspection. Oral vaccination is on its trial; if it should prove to be effective it will be a very useful means of protecting communities in which the disease shows signs of becoming epidemic.

The diagnosis of the disease is being simplified, the reaction of the stools, and examination of stained smears of the exudate give good working indications of the nature of the disease. Elaborate bacteriological methods have not proved satisfactory in practice, owing to the difficulty of obtaining fresh stools at an early stage of the disease and to the difficulties of the technique.

In addition to the well recognised sequelæ of the disease, attention has been called to the occurrence of a chronic peritonitis giving rise to ascites and it is believed that most of the cases which have formerly been diagnosed as cirrhosis of the liver in India are caused by improperly treated bacillary dysentery. There are also reasons for thinking that chronic parenchymatous nephritis may result from damage to the kidney by the toxins of the dysentery bacilli. It is not yet sufficiently clearly recognised that cases of bacillary dysentery should be handled on the same lines as typhoid fever, infection of contacts is just as likely to occur in India in bacillary dysentery as in typhoid fever.

Sprue.—This disease continues to be one of the mysteries of tropical medicine. It is probable that a close study of the conditions of life of the classes of the community which are chiefly affected might yield suggestions of value in determining the causes of the disease and the means of prevention.

Sprue is essentially a disease of the European and Anglo-Indian communities in India so that it is likely that there are certain factors which predispose these to the disease.

Possibilities are:—I. Intestinal stasis associated with a diet consisting largely of animal food and containing too little undigested residue. II. Overstimulation of the cells of the digestive organs which are called into special activity in the digestion of animal food. This over-stimulation may be followed by atrophy in the same way as happens to the islands of Langerhans in the case of the carbohydrate feeders in Bengal. Sprue might thus be analogous to the diabetes of

Bengalis. III. Climate and exercise must be taken into account, though these in themselves do not account for the disease.

The above suggestions are at any rate worthy of consideration, as attempts to show an association of the disease with special micro-organisms have not hitherto yielded satisfactory results.

The recently suggested treatment by parathyroid and calcium lactate has been widely tried in India, but the results are not so striking as in England, though further trials should be made.

Beriberi and Epidemic Dropsy.—Much of the work done during the past few years strongly tends to support the old view that these diseases are closely associated with rice intoxication, but the part played by vitamine deficiency is emphasised by most of the workers and the infection view has still its supporters.

Although there are some points which are still far from clear in connection with the disease, it is possible to lay down clear rules for its prevention. The diet of all persons should contain a sufficient amount of all the necessary vitamins, if this point is attended to the vitamine factor will be excluded. The rice that is used should be prepared and stored by methods which have been proved to be satisfactory by past experience, and if cases of the disease appear the rice supply should at once be changed, or better still rice should be excluded from the diet for a time, the suspected rice being used for animal food or destroyed. Indian experience shows that attention to vitamins alone is not enough to ensure freedom from the disease, rice preparation and storage appear to be the most important points in connection with the epidemic dropsy type of the disease. In practice person to person infection has not been found to be a factor of importance, but infection of the storage places of the rice cannot be ignored.

Hookworm Disease.—Treatment has received more attention than the other important aspects of the disease. Carbon tetrachloride appears to be the most powerful drug in hookworm disease. With reasonable precautions mass treatment with this drug can be carried out safely, and it is likely that periodical treatments will reduce the infestation of labour forces to a negligible quantity at a very small cost. The rare cases in which death occurs unexpectedly from the drug still await a satisfactory explanation.

Importance is now attached to the time of year at which the treatment is carried out. During the hot weather when soil infection is reduced to a minimum, a course of mass treatment is likely to cause a great reduction in the soil infection during the ensuing rainy season, whereas a similar treatment during the rains may be followed by rapid reinfestation of the persons who have been treated. It is hoped that investigation will be carried out on the important question of the degree of disability which is caused by hookworm infection in India. It is quite possible, for example, that 80 per cent. of a labour force may be

lightly infected without any serious diminution of efficiency, but no definite opinion can be expressed on this subject without carefully controlled experiments. There is a tendency to undue pessimism as to the result of preventive measures such as proper latrine accommodation. This has resulted from the tendency to record only percentages of carriers without taking into account the more important question of the average number of worms harboured by the individuals who are infected. When the reduction in the average number of worms which are harboured is taken into account, the value of latrines and mass treatment becomes much more evident.

The part played by pigs and other domestic animals in disseminating infection in the soil is receiving attention. Altogether there is still much to be learned about hookworm disease, and it is likely that if the efforts which are being made at present in different parts of the world are properly co-ordinated, accurate knowledge will be acquired more rapidly than has been the case in the past.

Filariasis.—The treatment of this disease is still unsatisfactory, no drug has been discovered which will destroy the parent worm without danger to the life of the patient. The part played by secondary infections is being studied and the treatment of these is likely to be greatly improved in consequence.

Guinea-worm Disease.—Guinea-worm disease is being closely studied in India. The clinical manifestations are being clearly stated and the rational treatment of the disease is being placed on a sound basis. The value of emetine as a cure has not been established and prevention still remains the most hopeful line of progress.

Cancer.—Cancer is too often regarded as a disease which is rare in the tropics, the truth is that certain forms of the disease such as the Kashmir *kangri* cancer, the betel chewer's cancer and cancer of the penis may be regarded as tropical diseases. A good many years ago the writer of this review had the hardihood to assert that many forms of cancer are avoidable and he called special attention to irritation as a proved factor of the greatest importance in the causation of the disease in India. At last irritation is receiving a due share of attention, but there was a remarkable degree of reluctance to accept irritation as an essential factor until the disease was experimentally produced in animals by the application of irritants. The comparative study of the incidence of cancer among different classes of persons and its association with special points in their environment is likely to yield important information in connection with the prevention of the disease.

GENERAL.

The year 1924 has produced much work of first class importance in the acquisition of knowledge of tropical diseases; there has been a great deal of clearing up of doubtful points and many lines of research have reached a position in which

there is great promise for the future. Co-ordination of research still leaves much to be desired but steady progress in this direction is being made. The conferences of medical research workers which have been held in Calcutta during the past two years have done much to secure this desirable object, but the Government of India and some of the local governments in India show a remarkable reluctance to encourage the interchange of visits between Indian medical research workers and those of other tropical countries, in spite of the fact that the cost of reciprocal visits is the merest trifle in comparison with the results which are likely to be obtained. In some directions the outlook is not so promising as would be suggested by the previous part of this note. There is a growing tendency on the part of some sections of the community to depart from scientific methods and to ask for a restoration of the systems of medicine which have had their day and which are utterly incapable of playing any important part in the progress of medical science. A study of these systems and a serious effort to discover what is of value in them is worthy of encouragement, but their reinstatement as accepted parts of the machinery of medical research and medical relief should not be undertaken until a thorough investigation has been made into their teachings and methods. Scientific medicine publishes its discoveries to the whole world, these are open to the fullest investigation and are not accepted until they have satisfied competent and critical investigators. An earnest search is being made to discover from every possible source better methods of diagnosis, treatment and prevention. The claims of every system of medicine must be subjected to a similar scrutiny before they can be accepted by reasoning human beings.

We must break once for all with the idea that scientific medicine is one of several competing systems, the use of the word "allopathic" to designate those who aim at the practice of scientific medicine is most objectionable. Medicine is rapidly becoming scientific and the part of it that remains unscientific is just as worthy of rejection as are the great masses of traditional beliefs which are held by the practitioners of the various systems of medicine.

There can only be one aim in scientific work, the discovery of truth and the improvement of existing imperfect methods. This aim can best be attained by following on the lines which have proved successful in all branches of knowledge, viz., those of accurate observation of facts and the formation of conclusions which are justified by the facts.

Medical education in some parts of India is passing through a critical period. The General Council of Medical Education and Registration has demanded that the medical examinations of the Universities of India should be inspected as a condition of continued recognition of the degrees; in Bengal this action has been challenged, with the result that the Medical Council no longer recognises the degrees of the Calcutta University.

The position of medical research in India is not so bad as might have been anticipated when the Inchcape axe descended on the Indian Medical Research Fund Association. What has happened is that the greatly needed expansion of medical research has been stopped, and the recruitment and training of the research workers of the future has been greatly hampered. Many of the most experienced research workers are retiring and suitable men who are not forthcoming to fill their places. The loss of the services of Lt.-Col. McCarrison to India was due to the curtailment of the funds of the Indian Research Fund Association. It is most important that systematic research into the dietaries of the people of India should be continued, and there is no worker who is more competent in this line than McCarrison. Those who will inevitably suffer are the people of India; it is in their interests that medical research should be organised and placed on a sound financial basis.

Another great need of India is the reorganisation of the medical forces which are at present engaged in medical relief and disease prevention. Nobody can for a moment argue that the existing medical personnel forms an army with an organisation which promotes the greatest efficiency. The members of the medical forces constitute excellent material, but they are employed to a great extent as isolated units working as best they can, and no adequate steps are taken to ensure that their efficiency is kept up to a high standard or that their efforts are co-ordinated. Praiseworthy experiments are being carried out in the formation of organisations for disease prevention and medical relief in certain small areas in India. It is essential that these should be thoroughly tested and that other experiments on well thought out lines should be made. Those methods which are found to be most effective should be extended on a definite plan. It is also essential that all medical men who are employed by Governments or by local bodies should receive periodical courses of training in modern methods of diagnosis, treatment and prevention of disease. These courses should be directed so as to bring up to date the knowledge of those who attend, with special reference to the duties which they have to perform.

The education of school children and students in the elementary laws of health should form a part of the curriculum of every school and college of India and a scheme should be worked out by which this education can be made effective. Even if no addition were made to the medical or educational budgets, it is quite possible to devise plans by which medical aid and disease prevention could be made vastly more effective than is the case at present.

Another point which cannot be lost sight of is that the economic condition of the people must be improved by encouraging more efficient methods of agriculture and industry, and that the general

education of the country should be directed towards fitting the children for their future careers.

The very important resolution which was unanimously carried at both of the conferences of medical research workers will doubtless bring about action by Government. This resolution called attention to the deplorable state of health and physical efficiency which prevails in India at present. It emphasised the great complexity of the problem of dealing with these and insisted on the urgent need for the appointment of a commission to examine the whole question. The appointment of such a commission would be likely to result in the formation of a definite programme and in the reorganisation of the forces which are engaged in the effort to better the physical and economic condition of India. Every one who has the good of India at heart ought to do his part in urging on Government the necessity for a serious enquiry into the real troubles of India. If the year 1925 should see the commencement of an investigation into the causes of ill-health and economic depression which exist in India, the outlook for the future is likely to become brighter than it has ever been in the past.

We have witnessed enormous advances in our knowledge of the prevention and cure of disease; what is most urgently needed now is the working out and putting into practice of a comprehensive scheme for the practical application of this valuable fund of knowledge.

Major Knowles and a distinguished band of collaborators have once again placed the whole medical profession of India under an obligation for the detailed summary of the advances which have been made throughout the past year in India, published as a supplement to this issue. It is only by reading such a review that one realises the greatness of the work which is being done. A spirit of co-operation is manifesting itself to an increasing degree, but we are far from the ideal of securing the help of every intelligent practitioner in India in the work of research. This is perhaps to some extent the fault of research workers themselves; they might do more to enlist the co-operation of the practitioners of India in their work and to dispel the too prevalent idea that research is the duty of a special priesthood of the profession. There ought to be a closer bond between research workers and general practitioners.

In this connection it is interesting to note that most of the really great discoveries of the past in India have been made by men who had little special training in research methods. Men like Sir Ronald Ross and Sir Leonard Rogers felt the inward impulse to research and no difficulties were sufficient to prevent them from following up their inspirations. Methods of research are becoming more and more specialised, but at the same time the facilities for training are vastly better now than they were ten years ago,

and apart from the highly technical forms of research there are many problems which could be solved by the co-operation of untrained workers, granted that they were given lines on which to make observations of the cases which come under their notice.

The *Indian Medical Gazette* has always done its best to encourage the spirit of enquiry among the men who hold the outposts in the profession; it is anxious to receive more papers which deal with clinical observations which will be of help to the general practitioner. The preponderance of papers which are published by trained workers is due chiefly to the fact that the general practitioners are holding back and are not sending contributions in such numbers as could be desired.

The limitations of space which have to be observed are hard facts, but the *Gazette* will do its best to find room for articles of a useful clinical type, and for practical suggestions for the improvement of our methods of dealing with the problems which are encountered by the general practitioner.

J. W. D. MEGAW.

Reviews.

BULLETIN NO. X OF THE INTERNATIONAL ASSOCIATION OF MEDICAL MUSEUMS AND JOURNAL OF TECHNICAL METHODS. New York: Paul B. Hoeber, Inc., 1924. Pp. 165. Price \$3.00.

THIS annual bulletin has recently appeared and is, as usual, replete with valuable articles and notes. It has added to its title and *Journal of Technical Methods* and this addition has been signalised by *Abstracts of Current Literature* dealing with macroscopic, microscopic, and bacteriological technique.

This section provides a very valuable supplement to the various manuals on technique which exist in all laboratory libraries, and is a welcome addition to the bulletin, previous issues of which were already highly appreciated.

Special articles in this bulletin deal with museum classification, and a method for the staining of many paraffin sections at one time, while there are several shorter original ones on museum and laboratory technique.

Laboratory workers and especially those concerned with museums are sure to find these bulletins of great assistance to them in the performance of their routine.

Curators of museums will also appreciate the Bureau for international exchange of material.

G. S.

HOME SEWAGE DISPOSAL.—By W. A. Hardenbergh, Major, Sanitary Corps, O.R.C. 82 Illustrations. Published by J. B. Lippincott Company, London. Obtainable from Messrs. Butterworth and Co., Ltd., 6, Hastings Street, Calcutta. Price 12s. net. Pp. 274.

THE problem of the disposal of human excretal matter is fairly easily stated; it consists in the conversion of a mixture which is offensive, putrescible, unstable and dangerous into something which is inoffensive, non-putrescible, stable, and safe; by means which shall at once be as free from nuisance and as economical as possible. The problem has existed since man's intelligence began to dominate his surroundings. The part most difficult of solution is the economical one, and

where the community of man is poorest, there are conditions worst and there will the insanitary symbiosis known as disease longer on longest. The present book is an attempt to cater for those who cannot obtain or afford the luxury of a proper water carriage system, but whose sanitary instincts and economic conditions are sufficiently advanced to imply willingness to expend a certain amount of their own money, time and attention on excretal disposal.

The book is mainly intended for rural districts in the United States; isolated houses, small communities and institutions being especially considered.

In India the service privy with subsequent collection and trenching of night soil is almost universal in most small towns, while in isolated villages excretal disposal is elementary, the Mosaic injunctions even not being observed.

The septic tank latrine and modifications like the aqua privy have been essentially Indian contributions to the problem.

Mr. Hardenbergh, who is Director of Rural Sanitation in Jefferson (Alabama), has been at great pains to produce an essentially practical book. Pit privies, box and can (commode), septic closets, Imhoff tanks, concrete tanks, chemical commodes, are all fully described and discussed, constructional details are given in full and illustrated by numerous excellent diagrams.

Most of these, we are afraid, would be beyond the means and capacity of Indian villages, but for schools and institutions the detailed plans and instructions are excellent. A description of the "deep pit latrine" which did such excellent service during the war practically everywhere, might with advantage have been included. We have not seen the "chemical toilet" used or suggested in India. In this the box contains a solution of caustic soda which sterilises and dissolves the excreta and will last a considerable time without attention.

The author is sanguine that the average householder could make his own "concrete vault" from the instructions given; perhaps he could in America, but we do not see the average Indian householder sawing his "lumber" to make "forms" into which he will pour his concrete correctly mixed by himself in the proper proportions of sand, cement and gravel. The directions given for the subsoil disposal of effluents are very clearly given with full details and illustrations of the methods of laying pipes and of filling in the filter trenches. We are of opinion that the book will be of very great value to all workers in public health and conservancy matters, both engineers and medical men. We read the book with great interest and profit.

MINOR SURGERY AND BANDAGING.—By Gwynne William, M.S., F.R.C.S., Surgeon, University College Hospital. 18th edition. Pp. 423, with 239 illustrations. London: J. & A. Churchill, 1924. Price 10s. 6d. net.

A book which has attained to the hoary antiquity of Heath's "Minor Surgery," to give this book its former title, has no need of the help of the reviewer to increase its popularity. First published in 1861, it has been revised every four years or so, and has now reached its eighteenth edition. It was the first of the house surgeon's manuals and it has never been surpassed for completeness, conciseness and accuracy. It is a book which the experienced surgeon may well make use of to refresh his memory when taking classes in practical surgery. The technique of aseptic surgery has not altered materially of recent years, and the treatment of infected wounds is much where it was left by the war. Kanavel's work on septic infections of the hand and his figures have been incorporated in an excellent section, which we welcome because the condition is so common and the new methods described are likely to give much improved results. The treatment of fractures by non-operative methods is dealt with in accordance with the

most modern ideas and we are glad to see the illustrations of the old splints superseded by those of modern ones. Delbet's method of treating fractures of the tibia and fibula has been included, a short section on the methods of employing skeletal traction has been given, and more emphasis has been laid on the use of plaster of Paris splints. We need hardly add that we recommend the book as heartily as ever, as a sound guide for house officers and junior practitioners at a very modest price.

FUNDAMENTAL PRINCIPLES IN TREATMENT.

By Dr. Harry Campbell, M.D., B.S., F.R.C.P. (Lond.). London: Baillière, Tindall & Cox, 1924. Pp. viii plus 477. Price 10s. 6d.

DR. HARRY CAMPBELL is one of the most attractive and readable authors whom we know; and this little volume is altogether admirable. In it is garnered together the accumulated wisdom of many years of medical practice, of teaching students, and of experience. If Osler's "Aequanimitas" is—as it deserves to be—a classic, this volume is a worthy second; for it deals with the physician and patient in their every individual and professional aspect. Did space but permit, we should like to quote from it wholesale. The subjects dealt with cover so wide and varied a range, however, that this is almost impossible.

On the education of the physician Dr. Campbell writes well; what is wanted is a sound general knowledge of the elements of his science and art, rather than braininess and specialism. Specialism indeed is now so elaborated that we read that in America, dental surgery is being split up into sections, one man devoting a lifetime of work to extraction, another to fillings, a third to dentures. He relates how a would-be aspirant, anxious to become a specialist on skin diseases, consulted one who had already attained to considerable fame in that line. The latter's definition of a skin specialist was one, the sound of whose name in any club would make all of its members involuntarily scratch themselves. The true teacher, he writes, should first learn the lesson of his own ignorance; once achieve that and the rest is easy; he will begin both to learn and to teach.

The physician's personality is next considered. He must have an iron constitution; the men who carry off the world's best prizes are those who maintain a high level of physical and mental health. Also sympathy and geniality are qualifications called for; tact, also, and business-like methods. Self-confidence is an invaluable asset, and the wisest physician is he who knows when to be silent; even a little humbug is useful, patients like it, and it is sometimes justifiable in the patient's interest. An old, but still amusing story here re-told is that of a famous physician who had prescribed grapes for a patient just before leaving the house. A servant was sent after him to ask for further particulars. The great man pondered deeply. Ten, and not more, he said, might be taken; but they must be white grapes and not black, and the pips should on no account be swallowed.

An admirable essay is that on thoroughness in examination of the patient. We all know the story of the visiting physician who enquired one morning of his house-physician how his patients were. "All doing well, Sir," replied the house man, "except the malingering, who died last night." A diagnosis of functional disease may sometimes be impossible to avoid, but it should not be given lightly.

Of consultations and consultants, Dr. Campbell writes very well. The worst type of "consultant" is the one who sees the patient independently, and subsequently tries to steal the case from the general practitioner in charge. Here the correct ethics of medical etiquette are rightly insisted on. Of quackery, he writes delightfully; instances given are the wife of an English ambassador energetically supporting the pretensions of one of the worst of cancer quacks; a distinguished writer of fiction who perished under the administrations of 'Christian Science'; an English Prime Minister who

declared the benefits of vaccination to be an open question. That quackery flourishes in almost every land is to be largely attributed to the exceedingly lax attitude of the lay press towards it; newspapers will accept almost any nostrum for advertisement, as long as it pays well.

The *vis medicatrix naturæ* being the physician's greatest friend and ally, we have to consider the relationship of instinct, reason and habits to treatment; most cases of chronic illness, indeed, shew a certain amount of adaptation to morbid conditions. The surgeon is in the fortunate position of knowing what is to be done and attempting to do it. With the physician the case is otherwise; he works partly in the dark, and his practice of medicine is still an admixture of what is rational and what is still empirical. Some given disease is perhaps amenable to treatment by several different means, and at present therapeutics is in a thoroughly unsettled state; "of all the inexact sciences therapeutics is probably at the present day the most inexact..... and this from the inherent difficulties which it presents." The result is that a wise attitude of conservatism is what is desirable; here and there a physician may go in for the latest fad and the newest "system," but he would be far better advised to hold to what is proved; "let him have fads, but let them be as broad-based as medicine itself." There are grape-cures, water-cures, raw-meat-cures, sunlight-cures, the mud-cure and a host of others; the mistake is to suppose that any one is universally applicable. In brief each patient is an individual problem, requiring individual study.

Following upon such introductory matter, come sections upon general principles, the plasma, sera and vaccines, septic foci, endocrines and enzymes, followed by six chapters on psycho-therapy. In this last section there is much interesting reading; the psycho-analysts, we read, have themselves largely to blame for the opposition which they have encountered; "much of their literature is frankly coarse. Admitting that to the pure all things are pure, there are ways and ways of presenting unpleasant truths." The influence of the emotions on health is profound; in the remote past ancestral man lived a life of excitement interrupted by intervals of boredom; to-day life is at a far duller level, the chief need is that for a livelihood, routine has replaced the chase, and matrimony, sexual adventures. But the inherent love of excitement is still inbred in modern man, as witness his love of gambling in any form. Hence the evil of melancholy surroundings in a sick room; the need to keep the patient, if fit for it, amused and entertained; "what would a really tame and harmless man, with no devil in him, be like?"

Sections follow on fresh air, ventilation, housing and clothing, exercise and diet. Modern diets of to-day, the author claims, are quite unnatural. When primitive man had to hunt for and capture his food, his diet was correct; to-day it is overburdened with carbohydrates and saccharides. "Cow's milk has been an enemy rather than a friend to British children in that it has favoured pap-feeding and driven hecatombs of them to a premature grave from tuberculosis." Sections follow on mastication, the care of the teeth, selection of diets, and physical nurture, and the book closes with an admirable set of aphorisms entitled "some important therapeutic truths," from which we cull the following:—"Keep well. Cultivate tranquillity and geniality. Be business-like. Keep an open mind. In examining a patient, be thorough; don't be hurried. Be consistent; be authoritative; give precise directions to nurse and patients; never blurt out such terms as cancer and cataract to a patient; when you find you have not your patient's full confidence, retire from the case. Common sense is a valuable asset in treatment. Avoid fussy interference with Nature."

We trust that we have done something to convey to the reader the charm and interest of Dr. Campbell's book; personally we found it entirely enjoyable and instructive.

CLINICAL METHODS.—By R. Hutchison, M.D., F.R.C.P., and H. Rainy, M.D., F.R.C.P. (Edin.), F.R.S.E. Eighth edition. London: Cassell & Co., Ltd., 1924. Pp. 688, 16 colour plates and numerous text illustrations. Price 12s. 6d. net.

THIS medical classic is not merely an aid, it is an essential to every medical student, and also a standard work of reference for the general practitioner. The eighth edition has been completely revised. Of the many additions made, the chief are sections on the fractional test-meal, Van den Burgh's test, the tests for estimation of sugar and of urea in the blood, and the urea-concentration test. The section on cardiographic methods has been entirely re-written with the aid of Dr. John Parkinson, and also re-illustrated. Many other new illustrations are included, whilst the colour plates are of a very high standard. Especially valuable are the colour plates of the appearances of the blood in different blood diseases and the anæmias, whilst the one of malarial parasites is both good and accurate. A new and useful plate is No. X, on the spectra of hæmoglobin and its derivatives. The figures of the helminthic ova, however, might be improved upon.

The new edition is certain of a wide circulation and we trust that it will receive a very warm welcome in India. It is very much up-to-date, and fills a niche in the medical student's or practitioner's library which no other book so exactly does; combining, as it does, bedside and clinical examination with laboratory and biochemical tests.

A MANUAL OF THE PRACTICE OF MEDICINE, PREPARED SPECIALLY FOR STUDENTS. By A. A. Stevens, A.M., M.D. 11th edition. London and Philadelphia: W. B. Saunders Company, Ltd., 1923. Pp. 645. Price 18s. net.

THE manual of medicine which has run to the eleventh edition has proved its popularity. It deals with all the diseases described in an elementary way. It is written in a very plain style and the arrangement is excellent. The pages dealing with tropical diseases, however, require further revision. With regard to kala-azar the statement "the mortality is said to range between 75 and 95 per cent." was only true before the antimony days. In connection with malaria "males are more often attacked than females" is apparently based on statistics of hospital-coming patients. "The pulse is accelerated in dengue fever" does not conform to the usual finding, which is just the reverse during the course of the disease. The page on beriberi describes the disease as seen in China and there is no mention of the epidemic dropsy form of beriberi which is very common in India. So far as other diseases are concerned the book is very useful and in fact it is a dictionary of medicine dealing with all the diseases, including the common diseases of the skin, which will be of great help to students preparing for examination, as well as for the general practitioner.

THE TREATMENT OF COMMON DISORDERS OF DIGESTION. By John L. Kantor, Ph.D., M.D. Illustrated. St. Louis: C. V. Mosby Co., 1924. Price \$4.75. Pp. 245.

THIS volume is intended to serve as a guide in the treatment of those forms of digestive disorders most commonly met with in the practice of medicine.

It is profusely illustrated with drawings and x-ray photographs and a start in treatment is made from the objective conditions thus revealed. This is a new departure, but it is obviously more sound than the empirical methods hitherto employed in these cases.

The book is written entirely from the practical point of view. The first chapter is devoted to general principles and methods, and deals with such subjects as general management, diet, gastric lavage, intestinal intubation, etc. Subsequent chapters deal with the question of ptosis, gastric irrigation, gastric and duodenal ulcer, delayed gastric emptying, constipation, achylia gastrica, gall bladder disease, diarrhoeas, and headaches associated with indigestion.

The style is clear and precise and the book is notably free from the verbiages of many American text-books. The paper, printing, and reproductions of skiagrams are worthy of the best traditions of the C. V. Mosby Co. It is essentially a work for the general practitioner, and we have no hesitation in recommending it as one of the best of its kind.

PEDIATRICS. By various authors. Edited by Isaac A. Abt, M.D. Complete in eight volumes. Vol. III. Pp. 1051, illustrations 223. London and Philadelphia: W. B. Saunders Co., Ltd. Price, Cloth 45s. net.

THIS volume maintains the same high standard of excellence as its two predecessors. It is essentially a book for the consultant. For the average general practitioner it is quite impossible to follow the standards laid down by the experts who contribute to the volume.

"The best is the enemy of the good," and what is needed for the practitioner in India is a clear statement of the best methods of diagnosis and treatment which it is practicable for him to carry out, rather than an account of the methods which are followed by highly specialised practitioners working under the conditions that prevail in London or New York. It does not help the Indian physician to tell him that the only treatment of hypertrophic stenosis of the pylorus is surgical; too often he cannot get a surgeon to operate, even if the parents of the infant are prepared to consider the question of operation. The statement that cases which are treated medically nearly always die will not be accepted by those who have experience of the medical treatment of such cases.

The author who deals with appendicitis in children is quite right in saying that there is no non-surgical treatment of the disease that can justify itself, but it is unfortunately true that cases of appendicitis in India often have to be treated medically, and it is also true that in such cases the mortality can be greatly reduced by skilful treatment.

The authors of this volume are American, with the exception of Pirquet who writes on the "nem" system of nutrition.

To all who have the time and the inclination to make themselves familiar with the modern advances in the management of children's diseases we can strongly recommend the purchase of Abt's "Pediatrics."

LIPPINCOTT'S QUICK REFERENCE BOOK FOR MEDICINE AND SURGERY. By George E. Rehberger, A.B., M.D., 4th edition. Philadelphia and London: J. B. Lippincott Co.

THE third edition of this book was reviewed so recently (April 1924) that it is not necessary to give a fresh description. The new edition has been brought up to date. It is very attractive and will be much appreciated by the general practitioner for whom it is specially intended.

The fact that the book has gone into a fourth edition since 1920 speaks for the great popularity of the work.

PHYSIOLOGICAL PRINCIPLES IN TREATMENT. By W. Langdon Brown, M.A., M.D., F.R.C.P. 5th edition. London: Balliere, Tindall & Cox, 1924. Price 10s. 6d. net. Pp. 511.

THAT this well known little book has reached its fifth edition in the short space of sixteen years is sufficient proof of its popularity. The application of physiological principles to the practice of medicine becomes more and more a practical necessity. The divorce of physiological teaching from the practice of medicine is now only insisted on by the old-fashioned empiricist. This little volume aims at creating that physiological outlook in medicine which the modern physician must possess.

Two new chapters have been added to the present volume, one on the liver and the other on asthma. There are also new sections on fractional test meals, insulin, uræmia and dyspnoea. These are all written in the author's inimitable style and form an important

addition to our conception of disease and methods of investigation and treatment which every up to date physician should know.

THE PROPHYLAXIS OF DIPHTHERIA BY THE DETERMINATION OF SUSCEPTIBLES AND THEIR ACTIVE ARTIFICIAL IMMUNISATION IN THE UNITED STATES. By Dr. Louis Van Boeckel, Director of the Laboratory of the Belgian Public Health Department. For the Health Organisation of the League of Nations. Geneva, 1924. Price 2s. 6d.

THE health organisation of the League of Nations is in a position of being able to accomplish work of importance to the signatory countries. Its funds can apparently be expended in investigating procedures in one country likely to be of use elsewhere, and health matters of international importance will more probably receive wider attention, trial and application than hitherto. With the discovery of the causal organism and method of cure, hopes of total elimination of a disease would seem to be reasonable. In the case of diphtheria this had not proved to be the case, and other aspects of the problem required intimate study before further progress in actual prevention became possible. The discovery of the bacillus in 1884 and of the antitoxin in 1890 have led, it is true, to a diminution in the case death rate by six-sevenths, but diphtheria morbidity in the United States has been reduced only by one-third and the case death rate still amounts to 8 per cent.

Carriers of virulent bacilli are numerous, their detection tedious and difficult, cases of diphtheria are not diagnosed early, antitoxin is given too late, sometimes insufficiently and sometimes not at all through anaphylactic fears.....these are some of the causes which led to the study of new methods of prophylaxis. The intensive study of the application of the Schick test of susceptibility and the immunisation of susceptible individuals by toxin-antitoxin mixture by enthusiastic workers in America, and the importance of the possibilities claimed led to a visit by a representative of the League of Nations to America, and the present report embodies Dr. Boeckel's observation and opinions.

It is an up-to-date critical résumé of the theories, principles and methods of application and results of these measures. A very complete bibliography is given.

Between 1911 and 1913 Schick demonstrated not only that the presence in the blood of a human being of 1/30th part of an antitoxin unit per c.c. rendered the subject refractory to diphtheria intoxication, but also that this quantity neutralized 1/50th part of a minimum lethal dose of toxin injected into the skin, so that no reaction occurred. If a human being reacts locally to the intradermal injection of 1/50th M.L.D. of toxin, his blood naturally contains less than 1/30th of an antitoxin unit per c.c. If the blood contains more than this, there is no reaction, the subject is immune. Park concludes that we are entitled to believe that a person with sufficient natural antitoxin to give a negative Schick reaction cannot contract diphtheria toxæmia or serious infection; further he thinks that apparent diphtheria infections in cases giving a negative Schick reaction are really streptococcal in nature. The preparation of the toxin best suited for the application of the test is discussed. Outfits are put up by Parke Davis & Co. and other well-known American firms and these outfits must conform to U. S. Public Health Service Regulations. Very full details of the technique of injection are given. The various types of reaction are also given, but the value of this part would have been enhanced by illustrations. Dr. Boeckel is of opinion that the value of the Schick test has been conclusively proved. Among 57,000 New York school children who gave a negative Schick reaction, Park noted only 5 cases of clinical diphtheria whereas 56 cases occurred among 90,000 other children, examined for comparison. As evidenced by the Schick test, susceptibility to diphtheria is slight during the first 6 months of life, becomes more pronounced between 6 months and 1 year, at which age it is highest in over 90 per cent. of children. It continues

to be strong until the age of 3, and diminishes progressively with age. Epidemiology has noted these facts previously, diphtheria occurring rarely at the beginning of life and in mature age, but frequently in children and rarely in adolescents and adults. Girls are more susceptible than boys. Well-to-do classes are more susceptible than those of thickly populated areas; similarly rural areas exhibit more susceptibility than towns.

Natural immunity once established is never lost, even after serious and debilitating disease. Natural contact with the diphtheria bacillus would seem to account for the immunity naturally acquired.

Most healthy carriers give a negative reaction, but a considerable proportion give a positive reaction. In the latter there is probably a local epithelium immunity.

After an attack of diphtheria, the Schick reaction does not always become negative. The earlier and more energetic the antiserotherapeutic measures, the less likely is the reaction to become negative. It would appear that early and complete neutralization of toxin destroys the stimulus necessary to create immunity. The Schick reaction has shown that artificial passive immunity given by anti-diphtheritic serum cannot be indefinitely prolonged by further injections; the more numerous the injections, the shorter becomes the period of additional immunity. The body tissues become educated to deal quickly with the foreign proteins injected. Several weeks is the limit of prophylaxis thus possible by passive immunity.

Active Artificial Anti-Diphtherial Immunization.—Attempts at active immunization of human beings by injections of diphtheritic toxin proved impracticable owing to violent local reactions and sometimes paralysis. A mixture of toxin and antitoxin, first in animals and later in human beings, was found to produce active immunization without local reaction. The immunity was produced comparatively slowly. Extended experiments have shown that the mixture should be carefully prepared and standardised so that untoward results may not occur. Well aged toxins and antitoxins are used. The L + dose of toxin is determined by titration with standard antitoxin and is the amount of toxin which, mixed with 1 unit of antitoxin, will kill a standard guinea-pig in 4 days. For immunization the toxin should be strong enough to contain 3 L + doses in less than 1 c.c. To the toxin mixture is added antitoxin and normal saline so that 3 c.c. of the resultant mixture given to guinea-pigs leads to the survival of these for more than 4 days.

The mixture is then filtered and kept until half the guinea-pigs injected with 5 c.c. survive for 10 days and only die slowly with paralytic symptoms. The product is then ready for use. The dose is 3 hypodermic inoculations of 1 c.c. each at intervals of 8 to 15 days; for children half the amount. Fractional inoculation is advised to those reacting strongly to foreign protein. The manner in which the mixture produces immunity is not known. Disintegration in the system would appear to be one explanation but does not explain all the facts.

American statistics appear to place beyond doubt the efficiency of prophylaxis of the measure. 500,000 diphtheria vaccinations have been carried out. The Schick reaction later becomes negative in cases previously positive. In 33,000 cases giving a positive Schick reaction, and immunised, only 9 cases of diphtheria occurred; in 90,000 used as controls 56 cases occurred. Immunity as shown by a negative Schick test develops in about six months, and lasts for life. No harmful effects have been observed. Between 6 and 12 months is the best age for active immunization.

Passive artificial immunization with antitoxin serum impedes active artificial immunization. Park recommends active immunization as a general measure of prophylaxis. Children between 6 and 12 months mostly give a positive Schick reaction and therefore at this age the test is unnecessary; universal active immunization carried out at this age period would definitely reduce

diphtheria mortality. After 3 years of age only susceptibles, as determined by the Schick test, need be immunised. These procedures have been taken up with American enthusiasm. It is evident that the toxin-antitoxin mixtures must be very carefully and very expertly prepared. The author is of opinion, however, that the older continent of Europe will be loth to accept a campaign on the same vigorous lines. There is no doubt, however, that where diphtheria is prevalent in endemic form the health services should apply these methods if they do not wish to be accused of neglecting to employ every possible means to combat the disease. The method was used successfully in a school in Shillong and it is as an institutional measure that in India, at any rate, these methods would seem to offer greatest scope.

The principles are capable of application in other diseases and already we have a "Dick" test for susceptibility in scarlet fever where a hæmolytic streptococcus is used.

A. D. S.

ORGANOTHERAPY IN GENERAL PRACTICE. Published by G. W. Carrick Co., New York. Pp. 253. Price \$2.00.

In these days of rapid advance in practical medicine much attention is being given to the study of different diseases from the point of view of the internal secretions and many a dark corner in the field of clinical diagnosis has been illumined by the application of the results of investigations into the functions of endocrine glands. It is no wonder, therefore, that a practising physician should be considered as being not up-to-date if he is lacking in knowledge of this most important branch of physiology. Recent researches in many diseases, especially some of the tropical diseases, tend to show that not a few of them have endocrine deficiency as their origin and their treatment will be much simplified if it is based on the correct recognition of the causal factor.

We welcome the publication of this book which deals with the entire field of organotherapy in a very practical and concise form. It is sure to prove very helpful to all medical men who want to adopt the modern principles of treatment in their practice. The chapters on the thyroid, pituitary, adrenals, sex glands, etc., are ably written and will amply repay perusal.

At the end of the book there is a complete and useful list of the organotherapeutic products of Messrs. G. W. Carrick Co. with their overseas distributors.

INTRODUCTION TO THE HISTOLOGY AND HISTOPATHOLOGY OF THE NERVOUS SYSTEM. By Dr. Paul Schroder. Translated from the second revised German edition by Baldwin Lucke, M.D., and Morton McCutcheon, M.D., of the University of Pennsylvania. London: J. B. Lippincott Co. Price 15s. net. Pp. 161. Obtainable from Messrs. Butterworth & Co. (India), Ltd., Post Box 251, Calcutta.

It is difficult to see what useful purpose this volume serves. The author describes it as "lectures introductory to the demonstration of microscopic preparations on the projection apparatus." It is not a textbook or a reference book. The illustrations are not helpful.

As a class book for students commencing a study of the histology and histopathology of the nervous system, it no doubt has its uses.

It is in the author's words "an introduction for those who wish to become familiar with the subject," and is designed as a stimulus to further independent investigations.

The style is lucid but the information given is not always complete, e.g., on page 91 the author writes "The nerve cells are highly differentiated elements; this fact may account for their inability to proliferate," whereas the fact is that nerve cells do not possess a centrosome, which accounts for their inability to undergo cell division.

THE CLINICAL EXAMINATION OF THE NERVOUS SYSTEM. By G. H. Monrad-Krohn, M.D., M.R.C.P., M.R.C.S., with a foreword by T. Grainger Stewart, M.D., F.R.C.P. London: H. K. Lewis & Co., Ltd., 1923. Price 6s. net. Pp. 148.

We have no hesitation in saying that this is the best six-shilling-worth in the whole range of medical literature. Its 164 pages are packed with clinical facts and tests, by the appreciation of which even the busy practitioner will be able to diagnose many obscure and otherwise puzzling nervous conditions. In a foreword Dr. Grainger Stewart writes: "Dr. Monrad-Krohn has shown his appreciation of the true needs of the neurologist and psychiatrist and has not confined his book to the purely neurological aspect of nervous disease but includes an outline of the examination of the mental state of the patient."

Dr. Stewart further points out that Dr. Monrad-Krohn is a member of the Royal College of Physicians, London, and so is well versed in the methods of the British School. As a Norwegian he has studied the subject in other countries and is thus able to present a scheme of examination of the nervous system based on a wide range of personal experience.

This is a little book which should be on the desk of every practitioner of medicine.

NEUROLOGIC DIAGNOSIS. By Loyal Edward Davis, M.S., M.D., Assistant Professor of Surgery, North Western University Medical School. London and Philadelphia: W. B. Saunders Co., 1923. Price 10s. net. Pp. 173. Illustrated.

In this volume, according to the author, an attempt has been made to present the subject of neurologic diagnosis from the view-point of correlating symptoms with known anatomical and physiological facts.

Sixty-two pages are devoted to the physiological and pathological variations in motility, gait, electrical reactions, reflexes, sensation, cranial nerves, aphasia, and disorders of speech, sympathetic nervous system and trophic disturbances. The treatment of the various subjects under the above heads is somewhat meagre and dogmatic, though on the whole correct.

The remaining pages, about 100, are taken up with illustrative cases, their discussion and diagnosis.

While in no sense a complete or even a comprehensive treatise on neurological diagnosis, it is a work which may be read with advantage by all who are interested in this subject.

CLINICAL STUDIES IN EPILEPSY. By Donald Fraser, M.D. Edinburgh: E. & S. Livingstone, 1924. Pp. 248. Price 7s. 6d. net. Postage 5d.

ALTHOUGH the author states in the preface that his book is not written for the expert or the laboratory physician, it contains a great deal that will be both interesting and suggestive to the professional psychiatrist. The clinical features of the book which will strike the reader as by far the most important are the case of a Mr. X and that of the author. The history of Mr. X has been kept by himself with painstaking accuracy and much insight for about thirty years. The clinical value of these remarkable observations is greatly increased by a report upon them from that amazing genius, Hughlings Jackson. In this connection we may be permitted to observe how entirely we support the author's contention that it is discreditable to British neurologists that the invaluable work of Hughlings Jackson should still lie buried in medical journals, whereby much of it is rendered inaccessible to the majority of the present generation of doctors. The author's own case is one of severe migraine which, to all who accept Hughlings Jackson's view of its nosology, must be classified as a sensory epilepsy. We are sorry to note that Dr. Fraser has nothing but scorn for the psycho-analytical conception of idiopathic epilepsy, and characterises the psychological interpretation evolved by Pierce Clark as a "grotesque fancy." The author's own hypothesis is that vaso-constriction is the initial movement in the epileptic seizure without which there would be no epilepsy

as we know it, although, he maintains, there must be other factors of causation besides the primary constriction of the blood vessels. There are a good many errata in the book, some of which are mentioned on a slip, but some others are not so indicated. For instance, the name of the town in Westphalia where there is a large epileptic colony should be spelt Bielefeld not Bielfield. Dr. Fraser has a novel system of employing the definite article which sometimes renders the book tiresome. The index, as might be expected in a work by a British author, leaves much to be desired. Perhaps one day British authors, especially of scientific works, will employ Germans to compile their indices, or, better still, go to Germany and learn there how to do it.

THE NERVOUS PATIENT. By Millais Culpin, M.D. (Lond.), F.R.C.S. (Eng.). London: H. K. Lewis and Co., 1924. Pp. viii plus 305. Price 10s. 6d.

This is an interesting and well-written book. The author is lecturer on psycho-analysis to the London Hospital Medical College, and, whilst a follower of Freud, he refuses to accept the wholly sexual explanation of suppression and repression advocated by Freud. During the war the War Office was compelled at last to pay very serious attention to the psychoses, to shell-shock and the like, and finally set up a centre for training medical officers in psycho-therapy at Maghull, and with this the author was associated. Hence he brings to the composition of this book a wide knowledge of the subject, together with a wide experience as a surgeon. And the results are well balanced and are interesting reading.

He classified the psychoses into conversion hysteria, anxiety states, obsessional states and actual neurasthenia. Psycho-analysis has thriven largely upon the opposition which it has encountered; to-day it bears two meanings and serves two purposes; it provides a theory of psychopathology, which strives to explain the ætiology of the psychoses in intelligible terms, and it provides a method of treatment. The author differentiates between suppression, which concerns material and memories which have once been present in the conscious mind; and repression proper, which is purely unconscious, and results from a struggle for supremacy within the unconscious of incompatible tendencies. In brief we have mental conflict at every cerebral level; which "may express itself at the psychic level of the nervous system as an obsession or a phobia, and at the sensorimotor level as a paralysis, a tic, a contracture or an anæsthesia; while if it sinks deeper down to the visceral level, it may express itself as glycosuria, exophthalmic goitre or asthma," to quote Dr. Langdon Brown.

The value of psycho-analytical treatment is proved by its success, the author claims. We are accustomed to admit as permissible any mode of treatment which is successful; even the virtues or otherwise of "therapeutic lying" were discussed in the *Lancet* a few years. How it works is not certain, but it is certain that the practice of formal suggestion, with the patient in a position of relaxation and a mental state approaching the hypnoidal, has successes. Suggestion therapy is often unconsciously used by every physician; if he were but trained to use it well and wisely his success would be greater as a healer of mental disorder.

From such an introduction, the author first analyses the minor psychosis, where he shews that such psychoses may be associated with physical causes and yet be independent of them in origin. Thus we have toxin theories, endocrine theories, blood-condition theories; according to Professor Swale Vincent "the continued and indiscriminate exploitation of the endocrine glands constitutes one of the worst forms of present-day quackery." That emotion has its bodily effects we all know; and here the author quotes the following delightful stanza from a hospital poet's *Ode to an Examination Candidate*:—

"Heed not the diuresis, that is but
The automatic signal of thy woe,"
and refers to mucous colitis, that "asthma of the colon," as being sometimes of emotional causation. Our

knowledge concerning the organic side of the minor psychoses is almost nil; hence psycho-analysis affords the best line of therapy.

Turning to hysteria, two main factors appear to be concerned in its aetiology; the loss of memory for experiences, the recollection of which is repugnant to the patient; and some motivation which is not within the patient's knowledge, and is not indeed always or often obvious to the observer. An account is then given of the bodily symptoms of hysteria and of the tests for the condition. Anxiety and obsessional states, the minor phobias in fact, tend to be concealed, until the patients are talked to frankly; often they are hidden under physical manifestations and completely overlooked. "The list of ailments in which a 'nervous' element exists is a long one; they are all of doubtful causation, and now that modern psychology can offer something to the understanding and treatment of them, the cases should be investigated from the point of psycho-pathology."

Ordinarily it is taught that functional disease is that in which no organic cause can be found; yet such a point of view is wrong; nervous disorder may accompany organic disease, it may even engender it; dismissal of a patient's trouble as "neurotic" does justice neither to the patient, nor to the science of medicine.

A chapter follows on practical instructions for the psycho-analytical examination of the patient, and then one on asthma and allied disorders. Both asthma and urticaria may in some patients be the equivalents of an anxiety attack; in fact we have here problems which involve both bio-chemical and psychological study. The epilepsy beginning in adolescence, the possibility of a psychogenic origin justifies an attempt at cure by analysis; in epilepsy associated with anxiety symptoms, the latter may be relieved by treatment, and some at least of the fits may prove to be hysterical; in cases where psychological examination demonstrates that the fits are hysterical or obsessional, the diagnosis of epilepsy must be put aside and psycho-therapy must be used." In gynaecological conditions the method has supreme value in the treatment of dysmenorrhœa, dyspareunia, and—above all—of the menopause. It is at least more promising than ovarian extract; "the amount of ovarian extract swallowed by women suffering from trouble at the menopause might be expected to lead to some definite appraisal of its value," writes the author, "but its use is still based upon hope."

The mental conditions and psychoses arising after trauma deserve far more careful study than they have yet received. Postural deformities and digestive and cardiac neuroses are often of psychic origin; "to persuade the owner of a protuberant abdomen to tuck in his belly, to throw out his chest and cock up his chin, is certainly a sounder procedure than to radiograph his intestinal tract after a bismuth meal and tell him that he is suffering from colonic stasis. Disordered action of the heart in the majority of cases is entirely of psycho-genetic origin," and should be treated as such.

In an additional chapter by Mr. W. S. Inman we have discussed eye symptoms of psychic origin; thus eyestrain is often of such origin; there is no definite relationship between the severity of the symptoms and the degree of refractive error; the wrong glasses may cure the patient, or the correct glasses may fail to cure. Often with regard to squint there is emotional instability. Left-handedness and stammering not infrequently accompany mental abnormality or psychoses.

In chapter 17, Dr. Stanford Read deals with the major psychoses as encountered in general practice, and here there is well outlined the rôle of the family physician as someone responsible, not only for the physical well-being of his patients, but for their mental health and for their mental and even spiritual advice as well as for the prescribing of drugs. Finally in chapter 18 we have outlined the general methods of treatment; and in

chapter 19 a most curious human document; a long letter written by a mental patient, for the authenticity of which the author vouches, and which conveys many lessons as to the inability of the ordinary and even specialist physician to deal with the mental case, and which is a document of curious and perhaps unique interest, almost the history of a lost soul, or at least of one who had tried many things of many physicians, and had failed to secure relief, and who was looking forward to the "seventh year" which perhaps would end it all.

Dr. Culpin's book is one which we would recommend to the attention of our readers. It is written from so broad a standpoint that it cannot fail to be of interest. Psycho-analysis appears to have a definite place in present-day therapy; but it would be better if the general practitioner exercised such an influence upon a basis of knowledge rather than of ignorance.

TRANSACTIONS OF THE AMERICAN PROCTOLOGIC SOCIETY, 1923. TWENTY-FOURTH ANNUAL SESSION. Edited by Maude E. Abbott, M.D., and Major James F. Coupal. New York: Paul B. Hoeber, Inc., 1924. Price \$3.00 net. Pp. 89.

We welcome the publication of these *Transactions* both for the summary of transatlantic progress in proctology with which they furnish us and for the reports of the breezy discussions on the papers. The speakers appear to know one another well enough to use the personal pronoun and to be very candid in their expression of their views, in refreshing contrast to the staid proceedings of British medical societies.

There is little that is new brought forward this year. Local anaesthesia is to the fore and appears to be steadily ousting general anaesthesia in the United States in this branch of surgery. Dr. Buie contributes a most interesting statistical summary of the Mayo Clinic observations on carcinoma of the rectum and pelvic colon, based on the records of 1,937 patients seen between 1910 and 1922. The figures show a steady rise in the percentage of operable cases to over 80 per cent. and a fall in operation mortality to under 10 per cent. Improvement in surgical technique and the increasing use of two-stage operations are mainly responsible for these results. That it is not to any great extent due to the patients being sent for operation earlier is shown by the sad fact that 18 per cent. of the cases operated on for carcinoma had had previous operations or treatment for hemorrhoids during the year previous to their admission to the clinic.

Dr. Clemons of Los Angeles brings forward an original treatment for rectal stricture by means of carbon dioxide snow, which many members expressed their intention of trying and of which we may expect to hear more next year.

ELEMENTARY HYGIENE. By Biharlal Lal Bhatla, M.Sc., F.Z.S., F.R.M.S., Lecturer in Zoology, Government College, Lahore; and Prem Nath Suri, M.B., B.S., Assistant Surgeon, King Edward Medical College, Lahore. Bombay and Calcutta: Longmans, Green & Co., 1923. Pp. 141. Price Re. 1-8.

THIS small book has been written to meet the requirements of matriculation students in the Punjab and other parts of India, where the subject of elementary hygiene is studied along with a course of physiology. From a perusal of the book, we can say that the authors have carried out their object well. Facts are clearly stated and in the recommendations and advice given, full cognisance of Indian conditions is taken. The only criticism that we offer is that the arrangement and style are rather suggestive of the "examination." Some of the illustrations might be improved. A "loctometre" is hardly a correct description; the picture of "how to sleep" on page 115 does not suggest ideal conditions; the arrangements for air circulation are meagre and no mosquito net is suggested.

MATERNITY AND CHILD-WELFARE. A National Problem. By A. Lakshmanaswami Mudaliar, B.A., M.D., Assistant Superintendent, Government Maternity Hospital, Madras. With a foreword by Major A. J. H. Russell, M.A., M.D., D.P.H., I.M.S., Director of Public Health, Madras. Madras: Everyman's Publishers, Ltd., 1922. Pp. 149. Price Re. 1-8. Obtainable from Everyman's Press, 1, McLean Street, George Town, Madras.

THE problem of the high infantile mortality in India is admittedly urgent; the appalling waste of human life that goes on in India cannot be right; the cold logic of the economist may state that a high infantile mortality is a necessary consequence of inflexible economic laws working on the human masses whose surplus vital energy produces but cannot maintain its numerous progeny. This may be so and it goes to the root of the problem; it is the economic conditions, the outlook and aspirations of the people that need looking to. It is one comfort to the practical sanitarian that his efforts against one particular disease are not limited but produce far-reaching results in other directions. Measures for the reduction of cholera lead to the reduction of other water-borne diseases, to habits of cleanliness and—what is most valuable—to a sense of civic responsibility both individual and collective, factors that go largely to the making of national character. Efforts to reduce the high infantile mortality in India hope not merely to preserve infant life, but to educate the masses in the eradication of dirty habits, in a cleaner mode of living, in parental responsibility, and to assist in that physical, moral and social uplift which is the line ordained by Nature for man's evolution.

Dr. Mudaliar in this book states the case for action clearly, vigorously and eloquently. It is specially intended for municipal bodies, which Dr. Mudaliar considers are the units most suited for starting work.

The layman on reading this book will not fail to be impressed by the descriptions of the conditions under which the average Indian mother, even in well-to-do families, undergoes her labour; he will find a clear account of what has been done in other countries, what is being done and what remains to be done in India; he will realise his own and his community's duties. Dr. Mudaliar's statements and arguments are intended for the lay public and therefore we would not too closely criticise some of his positive assertions. Australia requires population increase and grants £5 to every mother who gives birth to a child; but other countries are not in similar need. Not every one again views the low birth rate of France as a grave menace.

There are a few rather serious misprints; a typist from his political subconsciousness has advised "antenational care," and lovers of Dickens will be slightly shocked by the appearance of "Sarah Cramps."

For its purpose we thoroughly recommend the book.

NORMAL BONES AND JOINTS ROENTGENOLOGICALLY CONSIDERED. By Isidore Cohn, M.D., F.A.C.S. New York: Paul B. Hoeber, Inc., 1924. Price \$10.00. Pp. 218.

THIS book, the fourth volume of the *Annals of Roentgenology*, edited by Dr. James T. Case, is in reality an atlas of the bones and joints at different ages. The general scheme of composition is to begin with a review of the literature connected with the development and radiographic appearances of normal and injured joints, pointing out the fallacies which may arise from lack of knowledge of the normal appearances of the joints at different ages.

The type is large and clear, the reproduction of skiagrams leaves nothing to be desired. The omission of the Spanish and French translations provided in former editions is an advantage. Indeed the publishers are to be congratulated on having produced a book of unusual interest to the profession at large and a work of real utility to the roentgenologist and surgeon.

CLINICAL ASPECTS OF THE ELECTROCARDIOGRAM. By H. E. B. Pardee, M.D. With 56 illustrations. New York: Paul B. Hoeber, Inc., 1924. Price \$4.00 net. Pp. 222.

IN this volume the author has collected all the facts and current knowledge of the electrocardiogram which are of clinical importance. Experimental and theoretical considerations are included when necessary to the elucidation of the subject in hand, and are given in as simple a form as possible.

The earlier chapters deal with the normal electrocardiogram and the physiology of the origin of the electrical waves. Alterations due to various abnormal conditions are then discussed. After this the author deals with the various disturbances in rate and rhythm of the heart and the concomitant variations in the electrocardiogram. A whole chapter is devoted to the clinical application of the facts deduced from this method of examination. In the final chapters the theory of the electrocardiogram and the mode of installation and use of the apparatus is described and discussed.

This book should prove of immense value to the practising physician, who has no time to acquire an expert knowledge of this subject, and who has occasionally to deal with heart cases where this method of investigation is essential to the correct appreciation of the condition of the heart muscle and its prognostic significance.

DIATHERMY AND ITS APPLICATION TO PNEUMONIA. By H. E. Stewart, M.D. New York: Paul B. Hoeber, Inc., 1923. Price \$3.00 net. Pp. 210.

THIS little book deals with the medical and surgical aspects of diathermy, with special reference to the treatment of pneumonia. The early chapters are devoted to general technique and a description of the various types of apparatus employed. The later chapters deal with actual cases and the results and effects of treatment.

The literary style is clear and easy, the illustrations profuse and well executed.

The author has made out a good case for the further trial of this form of treatment in pneumonia, and it is to be hoped that others will give it a trial in this disease, which is rightly described as one of the greatest scourges of the human race.

A TEXT-BOOK OF CHEMISTRY FOR NURSES. By Fredus N. Peters, A.M., Ph.D. Second Edition. St. Louis: C. V. Mosby Co., 1923. Price \$2.50. Pp. 302.

THIS little book does not pretend to be a complete exposition of the science of chemistry. It is written in simple language and the author, while being scientific and truthful, has aimed at avoiding the technical, so that the matter may be understood by all for whom it is meant.

The text is profusely illustrated. Other features are the introduction of questions on the subject matter at the end of each chapter, and a number of interesting tables at the end of the book.

We can only say that it is a volume well worth the careful perusal of the nursing sisterhood interested in chemistry.

TRANSACTIONS OF THE FIFTH BIENNIAL CONGRESS OF THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE, SINGAPORE, 1923. Edited by the Hon'ble Dr. A. L. Hoops and Dr. J. W. Scharff. London: John Bale, Sons and Danielsson, Ltd., 1924. Pp. 974, 86 plates (2 coloured), and numerous charts in the text. Price 40s. net.

THIS excellently edited and printed volume constitutes a complete record of the Far Eastern Medical Congress held in Singapore in the autumn of 1923, which was attended by nearly a hundred delegates and representatives from all parts of the Far East. At the beginning of the volume there is a brief statement of the objects of the Association, followed by a list of delegates and representatives to the Congress, and members of the

Association. This is followed by the text of the address of welcome given by Sir Lawrence Guillemard, and the presidential address on "The Prevention of Disease in the Tropics" by Dr. A. L. Hoops. At the back of the book is a record of Council and business meetings, scientific meetings and social events, and excursions made by delegates to points of medical interest in the Federated Malay States. The remaining 900 pages contain the full text of 72 papers delivered at the Congress by men of renown from all parts of the Far East, with the discussions which followed them. The papers are grouped as follows: malaria 14, beriberi 7, ankylostomiasis 6, plague 4, leprosy 6, and miscellaneous, including one or more papers on nearly all the diseases of importance in the tropics, as well as some general papers, 35. It is impossible here to review, or even to name, the many valuable papers contained in the volume. Suffice it to say that many of them are of extraordinary interest, and constitute very important additions to our knowledge of the diseases which scourge the tropics. The editors are to be highly congratulated on the careful arrangement and attractive appearance of the book.

IMPERIAL SOCIAL HYGIENE CONGRESS. British Empire Exhibition, Wembley. May 12th to 16th, 1924. Organised by the National Council for Combating Venereal Diseases. 102, Dean Street, Oxford Street, London, W. 1. Pp. 286.

THE British Empire Exhibition, organised primarily to demonstrate the manufactures, products and resources of the Empire, brought together in England representatives from all parts of the British colonies and dependencies and gave an opportunity for the discussion of many subjects not necessarily considered in the exhibition. One such subject was what has been here called "social hygiene," otherwise known as the "social evil, the white slave traffic"; in plain language the moral and physical evils resulting from promiscuous sexual intercourse, the problems of venereal disease and prostitution. One may or may not approve of the publicity given to these subjects in medical, lay and what may be called the "Sunday" papers, but it is impossible to deny the benefit which has accrued to suffering humanity and to an innocent posterity from the dissemination of public knowledge of venereal diseases, their nature, dangers, and their cure.

Venereal disease has never been and indeed is now seldom correctly diagnosed and treated efficiently in its early stages by the general practitioner, and it is right that, in a matter so important to the public health, the State should make efficient diagnosis and treatment available for all. It is a notable fact that in England venereal disease stands conspicuous in being the one disease which an unqualified practitioner may not legally treat.

At the Conference, which lasted for five days, the subject appears to have been considered from every point of view. The present position in England is ably set out by Sir George Newman. The discovery of the causal organism of syphilis and later of a cure, and the development of the Wassermann reaction made it possible for diagnosis and treatment to be organised on lines which previously had been impossible. Public opinion became insistent that official measures should be taken, and in 1913 a Royal Commission was appointed and issued a report in 1916. Its recommendations form the basis of the present English organisation. Public Health Regulations made under the 1875 Public Health Act now give local authorities power to prepare schemes for the treatment of venereal disease and the Venereal Diseases' Act of 1917 provided for the suppression of quack advertisement and unqualified treatment. The schemes at present in force provide for (1) facilities for free laboratory diagnosis; (2) organisation of free treatment; and (3) public and professional education.

A full course of instruction is incumbent in every medical curriculum.

Compulsory notification and compulsory treatment are still subjects of discussion, while prophylaxis and methods of prevention by self-disinfection, being still subjects of controversy, have not been taken up by Government.

Dame Rachel Crowdy discusses the question of the international position with regard to prostitution and the suppression of the traffic in women and children. It is practically universally agreed that licensed houses should be forbidden; the inmates are practically slaves, all are sooner or later infected and as a result of the higher degree of promiscuity in licensed houses the danger of venereal contagion is greatly increased. The League of Nations is entrusted "with the general supervision and the execution of the agreements with regard to traffic in women and children." Prostitution as a domestic problem is therefore outside its sphere.

Sir Arthur Newsholme writes on "Some Aspects of Social Hygiene." He points out "the fundamental importance and sacredness of the family; that the guardianship of the germ plasm of the future, the passing on untainted of the inherent qualities of the family group is an essential duty of family life; that promiscuity, even in the absence of venereal disease, is the great enemy of family life."

Venereal disease is only a symptom of the trouble, which is deeper, more complex and difficult to understand and treat. We have not yet got behind Nature's purpose, if there is one. Multiply, multiply, she urges, with apparently no thought or provision for the consequences. To man alone has been given the gift of intelligence that he may try to understand the primal and ultimate intentions of Nature (should indeed these be). In a scholarly article Professor Mott writes on the "Psychology of Adolescence." The impelling influences developing in the young adolescent should on the one hand be kept from driving him into an abandonment to passion, and on the other from morbid introspection and wavering indecision. The normal adolescent may sow wild oats but will keep hold of the realities of life and remain a man of action. The first two types are exemplified in the impetuous Romeo and the melancholic Hamlet, while Henry V illustrates the third type. The adolescent female is absent from Shakespeare and is difficult of portrayal; the continental realists like Guy de Maupassant have successfully depicted her.

Other aspects of "social hygiene," e.g., "the general practitioner and the treatment of venereal disease," and "how to secure the maximum efficiency of a venereal disease clinic" are discussed fully, and a section is devoted to the consideration and description of the problem as it exists in various parts of the world under conditions naturally very varied. Representatives from India were insistent on the need for better education of the medical practitioner in India, and of the widespread incidence of venereal disease. Post-graduate education especially would seem to be necessary.

The book is issued by the National Council for Combating Venereal Diseases; and perhaps will be sent on application to those interested, as no price is given.

CORRIGENDUM.

IN our issue for last October, in the review of Dr. Wansleys Bayly's book "Venereal Disease, Its Prevention, Symptoms and Treatment," second edition, on page 523; for "Messrs. William Heinemann," please read "Messrs. J. & A. Churchill," who are the publishers. The information that the book is obtainable from Messrs. Butterworth & Co., Calcutta, is correct.

Annual Reports.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF BIHAR AND ORISSA FOR THE YEAR 1923. BY LT.-COL. W. C. ROSS, M.B., CH.B., D.P.H., I.M.S., AND P. F. PLOMER, A.M.I.C.E., M.R.S.I., PATNA; SUPDT., GOVT. PRINTING, BIHAR AND ORISSA, 1924. PRICE RS. 8.

Some extracts are given from this very instructive report.

THE preparation and publication every week of the vital statistics of all the municipalities in the province with a population of over 20,000 has been carried out throughout the year.

Weekly epidemic reports from all districts showing the number of seizures and deaths from cholera, small-pox, plague and influenza are also collected, summarised and circulated. The reports are published in the Government Gazette and also by the courtesy of the management in several newspapers of the province. By the publication of these statistics it is hoped to keep the public informed of the actual state of health of the large towns and of the prevalence of epidemic diseases in the districts, and to demonstrate the utility of vital statistics.

Col. Ross proposes to illustrate the value of vital statistics by some practical applications of their uses. In the cold weather of 1922-23 there was a fairly severe recrudescence of epidemic plague in Bihar. In October 1923, Government raised the question of arranging for plague preventive measures in advance for 1923-24. When the question was referred to Col. Ross, he was able to advise Government that extensive preventive measures were not likely to be required because the statistics of the last 19 years clearly showed that a year of recrudescence of plague was followed by a year in which the plague epidemic was much less severe and less widely spread. This proved to be the case and the plague mortality was exceptionally low. The second illustration happened after the end of the year under report. The statistics of the last 12 years have seldom shown that cholera was widespread or prevalent during the month of March. This year cholera was reported from all the districts of the province during March. Col. Ross was able before the end of March to report to Government, and to issue a general warning, that cholera was likely to be very widespread and very prevalent this year. Within a month or less of this report two very severe epidemics actually started in the Tirhut Division and in Shahabad.

In both these instances the careful study of comparative statistics extending over a number of years has proved of immediate practical value.

Periodicity in disease is discussed in the report.

Some diseases, such as plague and small-pox, are more regular in their recurrence, whereas malaria and cholera, which depend more upon favourable climatic conditions for their epidemic spread, are more irregular. It appears, however, certain that each violent epidemic is followed by a corresponding reaction in which the disease is much less prevalent than ordinarily, and that if local and other influences could be eliminated or allowed for, it would probably be possible to define accurately the periodicity of each disease. Each epidemic disease appears to have a different cycle of recurrence, the periodicity of which is based upon the immunity created in the population by the epidemic prevalence of the disease itself. In short it appears that the problem is fundamentally one in immunity, and that the periodicity of epidemic diseases depends upon the degree and the duration of the immunity which results from the general prevalence of the disease.

The price of rice which is the staple food of the province and which may be taken to indicate the general

trend of food prices, does not appear to vary much with the rainfall, and has risen in a most remarkable and consistent manner during the last 18 years.

The death-rate does not appear to be affected materially by the variations in the rainfall and prices, but appears to vary directly with the prevalence of epidemic diseases.

Famine would of course affect both the death-rate and the birth-rate, but famine has not been a factor of any importance during the period under review. The effect of high prices on the birth and death-rates has so far been largely neutralized by the sufficiency of the food supply. The points of outstanding importance demonstrated are that food prices have practically trebled in less than twenty years and that the birth and death-rates which are the basic measure of the public health have been but little affected owing to the sufficiency of the general food supply.

If public health is to improve, progress and effort are essential, and these imply organisation, the spread of knowledge, and expenditure. The expenditure is the immediate difficulty which has been allowed to dominate the situation too long. It appears to create a "vicious circle"—the people are poor because they are not healthy and they are unhealthy because they are poor; they cannot afford to acquire health; therefore nothing can be done.

This is where public health becomes an economic question. Let us not look only upon the difficulties nor be disheartened by the apparent impossibilities. But rather let us accept the proposition that public health is an economic question, and must be dealt with accordingly. Let us admit that we must have funds to meet the expenditure which we know must be incurred, if we are to make any real progress, and let us consider how we may obtain these funds rather than waste time in tinkering with the health of the people.

If we accept the general proposition that agriculture is the great national industry of this province and the only important source of its prosperity; then we must look to improvements in agriculture to increase the prosperity of the people and to provide the means for improving their health.

Some of the methods of dealing with cholera were:

(1) Special preventive measures were carried out by a special staff in connection with the Rath Jatra festival at Puri, and at Sonapur Fair.

(2) The use of chlorinated lime for disinfecting wells has now been generally adopted by local bodies and the procedure is generally known and appreciated.

(3) A special epidemic cadre of ten Assistant Surgeons was maintained. The headquarters of the cadre were at Patna, and these officers were sent out on epidemic duty throughout the province, whenever epidemic disease was prevalent. They were employed on plague duty in Bihar, and cholera duty at Puri and in Orissa and Bihar, and at other times they were employed in carrying out some investigation work.

(4) A special epidemic reserve of one hundred vaccinators was also entertained from 1st April to the end of September for cholera and other epidemic duty.

These men received a few days' training in the use of disinfectants and in the disinfection of wells, and were sent out by the Civil Surgeons with disinfectants and a few simple remedies whenever cholera was reported.

(5) During the year under report the training of vaccinators and *kabiraj*s in disinfection, and in simple preventive measures has been carried out, with the intention that village epidemics might be dealt with more promptly by local agencies.

(6) During the year 3,716 c.c.s. of cholera vaccine were received from Kasauli and stocked in the Vaccine Depot, Namkum, for issue as required. Three thousand, four hundred and fifteen doses were issued to Civil Surgeons and others on indents received.

(7) During the year a new scheme for a simple and cheap organisation for preventive measures against cholera and other epidemic diseases was issued to all local bodies and it is proposed that this scheme should be taken up as far as funds permit.

(8) At the same time, a leaflet on "Simple Instructions for the Prevention of Epidemic Diseases" was issued to all local bodies, the press and many Government Departments, and many District Boards and Municipalities have reprinted this leaflet in vernacular and distributed it broadcast through schools, sirpunches and other local agencies.

(9) Since the close of the year under report an extensive trial has been made of the use of kaolin in cholera with very satisfactory results. A circular was issued for general information giving details of the use of kaolin, etc., and District Boards and Municipalities have been circularised advising them to adopt this simple treatment which is safe, simple and cheap, and which can be given by any intelligent person.

Col. Ross holds that with the exceptions of particular areas and of epidemic invasions, malaria is not an important cause of mortality in the province of Bihar and Orissa, and that therefore the occurrences of epidemic malaria or influenza may be accurately estimated by any abnormal increase in the reported mortality from fevers.

The economic importance of malaria as a cause of debility, ill-health and ultimate mortality throughout the province is however great. The disease is endemic throughout the province, though to a varying degree in different districts, and it tends to become often epidemic in localized areas where the conditions are favourable to its transmission, and to become generally epidemic over larger areas at intervals.

In the opinion of Col. Ross it is not practicable to prevent malaria, or to reduce it permanently or on any large scale, by the use of quinine. The quantity of quinine required does not exist, and if it did, the people would not swallow it. Quinine is essentially a drug for the treatment of malaria as a disease, but it is not a means of stamping out the disease nor of preventing it on a large scale under existing conditions.

The adoption of non-productive anti-malarial operations such as draining, levelling, filling hollows and oiling water surfaces is also not a feasible means of prevention on a large scale over an enormous area. The staff which would be required to carry out such works and to maintain them would be enormous, and the expense would be colossal and prohibitive.

What is wanted is a policy of malarial prevention which will pay its own way and can be carried out in conjunction with other work of a productive nature.

Such a policy is already being carried out in Italy and Spain with extraordinary success. It consists in combining agricultural improvement with sanitation, by draining or flooding marshes and wet lands in a scientific manner so as to produce larger crops, and at the same time to reduce the breeding of transmitting mosquitoes and the spread of malaria. It also includes the cultivation of waste lands as far as possible and the intensive cultivation of good lands.

The history of plague shows that the disease recurs in epidemic form at intervals of about 70 years, persists for about 30 years or so, and then dies out altogether until the next epidemic comes round. The last two such epidemics are recorded and the occurrence of rat mortality and plague are referred to at frequent intervals in ancient history. We may therefore presume that plague will die out and disappear in due course and this is borne out by the definite, though irregular, decline in the plague mortality during the last fifteen years. It is therefore probable that plague will disappear in another ten or twelve years, and that there is little that we can do in the meantime to accelerate its

disappearance or diminish its prevalence except by the evacuation of infected houses and villages.

Two charts are published which show the effect of introducing piped water-supplies in the towns of Gaya and Bhagalpur. The death-rates from cholera, dysentery and diarrhoea were immediately reduced to about half of what they had been in previous years, and they have since remained at the lower level. This means an average saving of 700 lives from these diseases, chiefly the lives of children, in these two towns alone, every year.

The general prevalence of hookworm infection varies from 50 per cent. upwards to over 75 per cent. of the persons examined in the Patna Lunatic Asylum, in several jails and in the mining population.

Public Health Legislation.

Existing legislation is defective and inadequate in many ways and new legislation is very necessary if any real progress is to be made. Such legislation as is needed must be more simple, more concise, more comprehensive, and must give a strong and definite lead, with a view to requiring and directing a definite advance in public health standards and administration. The only question at issue is:—"How far is it wise to go?" It is admittedly useless to legislate too far in advance of public opinion, but on the other hand it is equally certain that legislation must either go in advance of public opinion and give it a lead—wisely and without undue pressure—or it must and will lag behind, in which case retrogression will take the place of progress, because of the arrest in the advance of public opinion, and the inertia engendered by the failure to use its influence and stimulate its growth.

It is essential to tackle the problems of public health more firmly and with a greater grasp, and to put forward a bigger and a braver policy of legislation and control.

The principles of public health are essentially the doctrines of socialism. The greatest good of the greatest number is the basis of both.

This is altruism, and man is not naturally an altruist, and will not take heed nor action until compelled thereto. It therefore rests with governments to control and care for, and to compel respect for the public health; and to this end there is a need for legislation to control activities, and education to instil knowledge. There is also a need for funds to finance the administration and work of public health; and to this end there is need to create wealth at the same time as expenditure, so that the burden may not become too great.

The initiative in all public health matters will usually rest with governments because there is no prospect of direct personal gain in such matters. The sad slow progress of public health is largely due to this, that it is "nobody's business" and that even governments are apt to neglect its needs for some more popular political demand.

Inasmuch as a nation consists of its people, and its strength is based upon their health and prosperity, so it would appear that the chief duties of any government are those dealing with the health and prosperity of its people.

In other words economic and public health considerations and requirements are fundamental and inseparable, and must be dealt with accordingly. Admit this and base policy upon it. Press for legislative reform and education. Encourage economic prosperity by making "two blades of grass to grow where only one grew before."

"And all other things shall be added unto you"—even Health.

Lt.-Colonel W. C. Ross is to be congratulated on a most interesting and suggestive report and on the excellent work which has been carried out by himself and his staff.

TRIENNIAL REPORT ON THE PROVINCIAL MENTAL HOSPITAL IN ASSAM, 1921-1923. BY COLONEL C. H. BENSLEY, I.M.S., INSPECTOR-GENERAL OF CIVIL HOSPITALS, ASSAM. SHILLONG: ASSAM GOVERNMENT PRESS. PRICE 8 ANNAS.

Lt.-Colonel J. W. McCoy, I.M.S., was in charge of the Assam Provincial Mental Hospital during the triennium until July 1921; Civil Assistant Surgeon B. N. Sen Gupta in July 1921, and Lt.-Colonel W. D. Ritchie, I.M.S., from the 22nd July, 1921. The total number of lunatics under confinement varied from 504 to 551, and shows an increase of some 20 per cent. over the previous triennium. Discharges numbered 53 per annum on an average. Escapes numbered 29, and 23 criminal lunatics were included among those incarcerated per annum. Nearly 28 per cent. of those admitted came from other provinces and were immigrants to Assam. Hindus numbered 73 per cent. of the patients, and Muhamedans 17 per cent. Males were to females as 5.17 to 1. Cultivators and tea garden coolies between the ages of 20 and 40 formed the largest group of patients. Mania and melancholia were the two chief types of insanity present. The death-rate in 1923 was very low, 6.75 per cent. of average strength as against a figure varying from 6.6 per cent. for Bombay to 10.23 per cent. for the Punjab. Influenza, dysentery and tuberculosis head the list of diseases responsible for admissions to hospital, and tuberculosis and pneumonia that of the death-rates. The average annual cost of upkeep was Rs. 84,007 as against Rs. 88,498 for the previous triennium. Profits on manufacture reached a sum of Rs. 13,612 in 1923. The average cost per inmate per annum amounted to Rs. 145 in 1923.

During the triennium one *pukka* barrack for 26 male patients was constructed, but this caused the temporary dismantling of a portion of the female temporary barrack, and reduced the accommodation therein available by 11. Special separate provision is made, as far as possible, for tuberculosis patients. The over-crowding is acute, however, and in Assam—as elsewhere in India—the old-standing scandal of confining non-criminal lunatics in jails for observation still exists. Influenza and malaria made for a somewhat unhealthy condition during the triennium, but the death-rate at this mental hospital is the lowest of any in India, with the exception of that in Bombay. There were 29 escapes during the period, 10 of them from inside the hospital; this last fact is largely due to the wearing out of the portion of the bamboo palisade surrounding the hospital, in the ground. Lt.-Colonel W. D. Ritchie, I.M.S., and Sub-Assistant Surgeon Mukhtar Hussain are mentioned as having done excellent work in the hospital during the triennium under review.

RAJA SIR RAMASWAMI MUDALIAR'S LYING-IN-HOSPITAL, MADRAS. REPORT FOR THE YEAR 1923. BY MAJOR W. C. GRAY, I.M.S., SUPERINTENDENT MADRAS: S. MURTHY & CO., 1924.

The total number of confinements was 1,747 during the year, and 4 other cases died undelivered. The largest number of confinements in any month was 173 in November. Primiparae constituted 24 per cent. of the cases dealt with, and 69 of the patients were sent in by the Madras Corporation Child Welfare Scheme. Natural deliveries totalled 1,023, difficult ones 151, pre-natural ones 44, and complex ones 529. No less than 97 were complicated with infective diseases, including 56 with malaria and 17 with dysentery. With regard to races and castes, 51 per cent. were Hindus, 27 per cent. Adi-dravidas, 16 per cent. Indian Christians, and only 3.5 per cent. Muhamedans. The total number of maternal deaths was 43, including 23 cases admitted in a moribund condition, with a death-rate of 0.86 per cent.; a statement which shews the high standard of the work

carried out in this hospital. Ankylostomiasis with profound anæmia accounted for 7 deaths after delivery. Fœtal mortality was only 4.5 per cent. of the number of live births; 577 non-obstetrical cases were also seen.

Eclampsia occurred in 28 cases,—20 of them primiparae. The treatment adopted was a conservative one, assisting labour when absolutely indicated, and injections of veratrine if the blood pressure was above 130 mm. One case of triplets and 32 of twins occurred among the 1,747 labours. One patient was admitted with complete rupture of the uterus, already 48 hours in labour, and died after hysterectomy. There were 77 cases of abortion. The percentage of live births after forceps operation reached the high total of 95.4 per cent., a figure some 4 to 5 per cent. above that for any previous year. Podalic extraction was resorted to in 7 cases, 5 times for extended breech presentation, once for foot presentation with eclampsia, once in a case of head and foot presentation, with descent of the funis. Perforation was resorted to in 8 cases; the indications being a brow presentation with death of the fœtus, small round pelvis, contracted flat pelvis, an elderly primipara with prolonged labour, and a brow presentation with prolapse of the arm and funis. Cesarean section was only resorted to once, for contracted pelvis. Fifteen pupils attended the institution during the year for practical training in midwifery.

DISPENSARY RETURNS OF THE PROVINCE OF ASSAM, 1923. BY COLONEL C. H. BENSLEY, I.M.S., INSPECTOR-GENERAL OF CIVIL HOSPITALS, ASSAM. SHILLONG: ASSAM GOVT. PRESS. PRICE RE. 1.

The year opened with 246 hospitals and dispensaries, and closed with 227, 1 being opened and 20 closed during the year, including 15 travelling dispensaries, which were closed on the ground of economy, and especially as their efforts had not met with much success. The number of patients treated totalled 1,599,594 during the year. In-patients numbered 10,732, with a death-rate of 9.30 per cent. The principal causes of admissions to hospital were kala-azar, eye diseases, injuries—local and general,—ulcers, malaria and dysentery. Kala-azar patients numbered 789 in-patients and 10,616 out-patients, as against figures of 414 and 5,472 for the previous year; but this of course only represents a small fraction of the kala-azar work in the province, since the kala-azar survey staff treated some 35,000 cases in Assam during the year. With regard to caste, of the 1,599,594 patients treated, 811 were Europeans and Anglo-Indians, 813,397 Hindus and 560,978 Muhamedans. The total number of surgical operations was 17,703, with a cure rate of 98.08 per cent. and a death-rate of 0.34 per cent. Selected operations numbered 901. The income of the state-public, local fund and private-aided dispensaries was Rs. 7,46,368, of which 59 per cent. was found from provincial revenue, and subscriptions and donations amounted to only 5 per cent. The total expenditure was Rs. 6,07,896. All dispensaries in the infected areas are now fully equipped to deal with kala-azar cases, and the closest co-ordination has been secured between the extensive kala-azar survey under the Public Health Department and the kala-azar work in the hospitals and dispensaries under the Medical Department.

On the whole the year was a healthy one, except for the steady persistence and slow spread of kala-azar. All district boards and municipalities, however, are experiencing very great financial difficulties, and Colonel Bensley appeals for a larger measure of private support. "It is not fair on the medical staff that they should not have the means at their disposal to treat cases properly. It would be better to close a dispensary than to practise what really amounts to a deception on the poor people who come to it with absolute confidence." Finally Colonel Bensley remarks on the extreme pressure of work on all the Civil Surgeons in the more important districts of the province.

KING EDWARD VII MEMORIAL PASTEUR INSTITUTE, SHILLONG. 7TH ANNUAL REPORT FOR 1923. BY LIEUT.-COLONEL E. D. W. GREIG, I.M.S. SHILLONG: ASSAM GOVT. PRESS, 1924. PRICE 12 ANNAS.

THE year 1923 at the Pasteur Institute at Shillong was chiefly remarkable for the frequent changes in personnel. Major H. E. Shortt, I.M.S., officiated as Director from January 1st to 15th; Lt.-Colonel F. P. Mackie, O.B.E., I.M.S., from January 15th to March 24th; Major Shortt again till June 10th; and Lt.-Colonel E. C. Hodgson, D.S.O., I.M.S., from June 11th till the end of the year. Possibly as a result of this, and of a still further change in the directorship since the end of the year, the report for 1923 consists chiefly of statistics.

In all 2,371 patients were treated; in fact the rise in the figures is enormous; in 1917 the number treated was 569; in 1922 it reached 1,728, in 1923 it increased again by some 35 per cent. Europeans treated numbered 150, and "advice cases" which did not require treatment numbered 146. There were 22 deaths from hydrophobia, or a total hydrophobia mortality among the treated of 0.93 per cent., a very low figure when it is noted that jackal bites numbered no less than 490 of the 2,371 patients treated or 21 per cent. of cases, and were responsible for 6 deaths from hydrophobia of the 22. Jackal-bites, which are not seen at the Rangoon Pasteur Institute, and which are relatively few at the Coonoor Institute, are a marked feature of the population treated at Shillong, and the low hydrophobia rate recorded in spite of this fact is very satisfactory. The "failure rate," i.e., percentage of persons treated who developed hydrophobia more than 14 days after completing treatment, was only 12 deaths out of 2,371, or 0.51 per cent. None of the Europeans treated developed hydrophobia.

Of the 2,371 patients treated, 950 came from Assam, 1,361 from Bengal, 56 from Bihar and Orissa and 4 from the Central Provinces.

Turning to the bacteriological, clinical and research side of the Institute, no less than 11 papers were published during the year by Major Shortt, most of them in connection with the kala-azar investigation. The kala-azar patients treated numbered 84, together with 22 cases sent to the Institute as suspected kala-azar cases, but where the diagnosis was not kala-azar. Of these 84 cases, 65 were discharged cured, 5 left before treatment was completed, 7 died, and 7 remained under treatment at the end of the year. Urea stibamine was used to a large extent, and as our readers know already, the reports on its use are very favourable. Bayer's 205 and urotropine proved useless in the treatment of kala-azar. Assistant Surgeon Ram Taran Sen was in charge of the kala-azar hospital throughout the year.

The work of the Shillong Pasteur Institute on diphtheria in the boarding schools in Shillong has already been published in our columns. The Schick test was introduced into India for the first time and the disease is now fully under control, and the year 1923 was the first since 1917 when the boys' and girls' schools at Shillong were free from this infection,—one which is usually rather prevalent in boarding schools in hill stations in India. Of 242 children examined in 1923, 16 were found to be carriers, 4 of them harbouring virulent strains. The vaccine section, which is now only a distributing centre, sent out 18,585 c.c. of anti-influenza vaccine during the year; 71,630 c.c. of anti-cholera vaccine, and 748 c.c. of anti-enteric "T.A.B." vaccine.

The report closes with the usual detailed statistical tables. These were first introduced into Pasteur Institute work in India by Lt.-Colonel W. F. Harvey, C.I.E., I.M.S., in 1912, at Kasauli. As a result, there has now accumulated such a wealth of accurate, detailed and reliable information with regard to the problems of "dog-bite" that we wonder whether the time has not now arrived for this enormous mass of collected statistical evidence to be sifted by some mathematical and

epidemiological expert. The information thus laboriously collected for some 12 years covers some hundreds of thousands of patients, and its analytical study should yield information of very great value.

Correspondence.

GANGOSA IN INDIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I was greatly interested in the case of gangosa reported in the *Indian Medical Gazette* for August 1924 by Mr. H. T. Holland, from the C. M. S. Hospital at Quetta, and in Col. Tyrrell's letter in the November number of the *Gazette* describing a case of the same disease seen and treated by him in Malwa, Central India, some fifteen or sixteen years ago.

Nearly eight years ago, I detected a case among the inmates of the Acworth Leper Asylum at Matunga in Bombay, and described it with a photograph in an article on gangosa in the *Indian Medical Gazette* for February 1917. The article not only gives a detailed description of the disease, but I have in addition fully discussed therein the various views held with regard to its causation; a complete list of the literature then available on the subject is also given. Under the heading, geographical description, my remarks run as follows:—"I can find no record as to the existence of this disease in India; it is however probable that it does exist in this country and is mistaken either for syphilis or leprosy."

Soon after the publication of that article, a medical practitioner from the Central Provinces sent me clinical notes of two cases of gangosa, which he came across, if I remember rightly, in the city of Nagpur. Unfortunately the correspondence has been mislaid.

It would be interesting to know if any other cases have been recorded, for there is now every reason to believe that gangosa does exist in India, but is mistaken for either leprosy or syphilis. The photographs published in Mr. Holland's paper and in my article might help in the detection of this curious tropical disease, the etiological factor of which is still unknown.—Yours, etc.,

D. A. TURKHUDD, M.R.C.M. (Edin.),
Acting Director, King Institute.

GUINDY, MADRAS:
18th November, 1924.

INTRAVENOUS IODINE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Since my article on intravenous iodine was published in your columns, I have been receiving letters enquiring about the actual preparation of my solution. As it is not possible to reply to these individually, I ask your permission to publish the formula, which is as follows:—

℞
Iodine .. 1 drm.
Pot. Iodide .. 1 drm.
Aq. dest. .. 5 ozs. 2 drms.

The iodine is dissolved in the solution of potassium iodide in distilled water, previously prepared.

Adult dose—3 to 6 minims given intravenously.—Yours, etc.,

J. C. CHAUDHURI, L.M.S.,
Vice-Chairman.

DISTRICT BOARD, BOGRA:
2nd December, 1924.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In your November issue two articles have appeared by Dr. P. Bell, I.M.D., and Dr. J. C. Chaudhuri on the value of intravenous iodine.

I have used intravenous iodine since 1909 when at the Remount Depot, Mona (Punjab), for the first time with very encouraging results, and in private work it is the very first drug for me. Recently, I had an

FEB., 1925.]

opportunity to use it in a case of acute phthisis with severe hæmoptysis, and the only suggestion I have to offer in iodine medication is to always combine it with adrenaline solution (1 in 1000) m.x. to 1 c.c. Also I have always preferred to use normal saline solution rather than either rain or distilled water. The aqueous solution is a hundred times better than the spirituous, and this should be obvious to any scientific worker.—Yours, etc.,

B. J. BOUCHE,
Asst. Surgeon, I.M.D.

JUTOGH, SIMLA HILLS:
13th November, 1924.

Service Notes.

APPOINTMENTS AND TRANSFERS.

The services of Lieutenant-Colonel T. C. McCombie Young, M.D., I.M.S., are placed at the disposal of His Excellency the Commander-in-Chief with effect from the 20th November 1924.

Lieutenant-Colonel N. M. Wilson, O.B.E., I.M.S., made over charge of the duties of Superintendent of the District Jail at Ambala to Major B. Gale, I.M.S., on the afternoon of the 19th November 1924.

Lieutenant-Colonel H. C. Keates, I.M.S., made over charge of the duties of Superintendent of the District Jail at Lyallpur to Lieutenant-Colonel R. T. Wells, I.M.S., on the forenoon of the 28th November 1924.

Major F. Stevenson, I.M.S., an officiating Agency Surgeon, is posted as Agency Surgeon, Gilgit, with effect from the 3rd November 1924.

The services of Major H. Stott, O.B.E., M.D., I.M.S., are placed temporarily at the disposal of the Government of the United Provinces with effect from the date of his appointment as Professor of Pathology, King George's Medical College, Lucknow.

The services of Major T. D. Murison, I.M.S., are placed permanently at the disposal of the Government of Assam with effect from the 20th November 1924.

The services of Captain C. de C. Martin, M.B., I.M.S., an officer of the Medical Research Department, are placed temporarily at the disposal of the Government of Madras for appointment as Officiating Assistant Director, King Institute of Preventive Medicine, Guindy, with effect from the date on which he assumes charge of his duties.

The services of Captain R. C. Malhotra, O.B.E., I.M.S., are placed permanently at the disposal of the Government of the Punjab with effect from the 4th April 1924.

LEAVE.

Lieutenant-Colonel A. C. MacGilchrist, I.M.S., Civil Surgeon, is allowed leave on average pay for two months, with effect from the 3rd November 1924.

Captain J. E. Dhunjibhoy, M.B., I.M.S., Superintendent, Central Mental Hospital, Berhampur, is allowed extension of leave for eighteen days.

Lieutenant-Colonel O. St. John Moses, M.D., I.M.S., is allowed leave on half average pay for four months, in extension of the leave granted to him in Notification No. 2867-Medl., dated the 5th September 1922.

Major L. H. L. Mackenzie, I.M.S., an officiating Agency Surgeon, is granted leave on average pay for 8 months combined with leave on half average pay for 1 year and 24 days, under Fundamental Rule 81, with effect from the 3rd November 1924.

PROMOTIONS.

Lieutenant-Colonel to be Colonel.

Robert Welland Knox, D.S.O., M.B., F.R.C.S., I.M.S., vice Colonel Harold John Kinahan Bamfield, D.S.O., K.H.P., I.M.S., promoted to the rank of Major-General, with effect from the 24th September 1924. Colonel Knox's tenure of appointment will count from the 3rd October 1924.

The promotion to his present rank of Major H. B.

Scott, O.B.E., F.R.C.S.E., I.M.S., is antedated from the 1st September 1918 to 1st March 1918.

The promotion to his present rank of Major A. N. Thomas, D.S.O., M.B., I.M.S., is antedated from the 27th July 1919 to 27th January 1919.

RELINQUISHMENT OF RANK.

Major W. D. H. Stevenson, M.D., D.P.H., C.I.E., I.M.S., relinquished the temporary rank of Lieutenant-Colonel on vacating the appointment of Assistant Director-General, Indian Medical Service on 10th February 1922.

Captain (Acting Major) W. E. Brierley, I.M.S., relinquished his acting rank on the 31st January 1920 (afternoon) on substantive promotion to the rank of Major, with effect from the 1st February 1920.

RETIREMENT.

The King has approved the retirement of Major-General J. Jackson, C.I.E., M.B., K.H.P., I.M.S., from the 24th September 1924.

NOTICES.

NUJOL.

"CHRONIC mucous colitis"—of whatever origin—is one of the bug-bears of medical practice in India. Neglected and chronic amœbic or bacillary dysentery, viscerotoposis, chronic intestinal stasis with all its attendant complications, perhaps serve to explain the great frequency of this condition in tropical medical practice.

When faced with such cases the medical practitioner is often puzzled to know what aperient to prescribe. We consider that there can be only one answer; liquid paraffin or some other absolutely non-irritant and mechanical purgative. In all conditions of intestinal stasis, as well as in the intestinal tuberculosis which is so common in India, liquid paraffin is indicated as the best of aperients. "Nujol," a product of the Standard Oil Co. of New Jersey, it is claimed, presents liquid paraffin in pure form as an intestinal lubricant. It is claimed that it is entirely unacted upon by the intestinal ferments, is not absorbed, and it has been advocated by Dr. J. H. Kellogg in his book on "Colon Hygiene." In the course of preparation the product is finally held in glass-lined tanks, from which samples are withdrawn for tests as to purity and chemical composition. Lastly, it is claimed that its continued use in the habitual constipation of women is free from all the customary difficulties of increased dosage and absolute dependence attendant upon the use of other purgatives. The Indian agents are Messrs. Muller and Phipps, 21, Old Court House Street, Calcutta; and 14 to 16, Green Street, Bombay.

PSICAINE; A NEW LOCAL ANÆSTHETIC.

An announcement by the celebrated firm of E. Merck & Co., Darmstadt, of the discovery of a new and non-toxic local anæsthetic with twice the potency of cocaine, and free from many of the dangers attending cocaine administration, will be of special interest to our readers. Psicaine, the new local anæsthetic thus discovered, is a synthetic product, not derived from the leaves of the cocoa plant, but an isomer of cocaine with similar and yet dissimilar properties. So far, in England and under the Hague Opium Convention Act of 1912, it has not come under the rules applied to opium and cocaine, whilst the drug is at present under investigation by the British Ministry of Health. There are theoretically possible twelve isomers of cocaine, of which at present six have been synthetically prepared in Messrs. Merck's laboratories at Darmstadt. Psicaine is the acid tartrate of the dextro-rotatory pseudo-cocaine; viz., d-4-cocaine, and is a white, crystalline powder soluble in four parts of water, but less readily soluble in alcohol. The aqueous solution is acid, has a bitter taste, but when placed upon the tongue produces prolonged numbness. Its solution will bear sterilisation at 110°C. without decomposition.

It is also more soluble in lipoids than is cocaine, and therefore might be expected to have a greater anæsthetic value.

On experimental tests, it is claimed that this compound has twice the local anæsthetic value of cocaine, with no symptoms of accumulation or intoxication in experimental animals. Apparently it is also more rapidly excreted from the system. It is a vaso-dilator, rather than a vaso-constrictor, and its absorption from mucous membranes appears to be gradual. Beringer and Williams report that in doses which correspond it does not cause nausea or collapse, as does cocaine, and it does not produce the same feeling of euphoria.

Hitherto cocaine has held its own against all attempted substitutes, but psicaine may apparently come to replace it. It is recommended for rhino-laryngological work in a solution of 5 to 10 per cent.; for urological work in a solution of $\frac{1}{2}$ to 1 per cent.; for ophthalmological work in a 2 to 5 per cent. solution. It should be used exactly as is cocaine, and adrenalin may be added to the solution. At present it is available only in powder form in bottles of 1, 5, 10 and 100 grammes, and the Indian agents are Messrs. Martin & Harris, 8, Waterloo Street, Calcutta. The *Chemist and Druggist* drew attention to this new compound in an editorial article in its issue for the 12th of July 1924, whilst several reports by German and other workers speak of it very favourably.

Finally, it is claimed that there is here a drug which may be of value in cure of the cocaine habit. Willstätter, the distinguished Munich chemist, has analysed the cocaine molecule and has shewn, in a series of researches lasting for some years, that there may be many isomeric forms. Gottlieb has suggested the experimental use of some of these isomers. Psicaine is dextro-rotatory, whereas cocaine is levo-rotatory, whilst the former was found to have only one-half of the toxicity of the latter. Whereas cocaine is excreted through the kidneys after administration, psicaine is not—except in minimal quantities, and is apparently decomposed within the system more rapidly than is cocaine. Under such circumstances it may become a useful substitute for cocaine in cases of cocaine addiction.

The drug is clearly at present upon experimental trial; but future reports as to its clinical value will be awaited with interest.

CALCIUM METABOLISM IN TUBERCULOSIS.

AN interesting report in the *Organotherapeutic Review* for October 1924 deals with this subject. Dr. H. R. Harrower in 1913 advocated administration of splenic substance in cases of tuberculosis, following the lead of Bayle in 1912 at the International Congress on Tuberculosis held in Rome in that year. In a batch of rabbits inoculated with spleen nucleo-protein solution at the Harrower Laboratory it was found that the injections had been followed by a considerable increase in the ionic calcium content of the blood. It has long been known that administration of parathyroid extract is followed by a similar result, and parathyroid therapy has now taken its place in the treatment of tetany, sprue, and other diseases where there is apparently a deficiency in the blood calcium content, but the action of splenic extract was found to be even more marked; in some instances as much as an increase of 3 mgms. of blood calcium per 100 mls. of blood having been noted. Further the blood was rendered more coagulable.

In tuberculosis calcium loss is the rule. In all states of chronic ulceration accompanied by parathyroid deficiency it is now customary to prescribe parathyroid extract, whilst the splenic extract appears to be even more efficacious. The Harrower Laboratory (Endocrines, Ltd., Simla), have accordingly placed upon the market two preparations;—Parathyroid Co. (Harrower), which contains parathyroid extract together with desiccated splenic nucleo-proteid, and Solution Para-Spleen Co. (Harrower), which contains a 4 per cent. solution of the active extract of parathyroid and splenic glands

for hypodermic injection. The former, it is suggested, is suitable for oral administration, and the latter for hypodermic administration, in graduated doses.

That calcium metabolism is intimately bound up with the problems of the successful therapy of tuberculosis appears to be certain, and any advance in such investigations is to be welcomed.

FORESIGHT IN PHOTOGRAPHY.

FRESHNESS appears to be as much an attribute of Burroughs Wellcome & Co.'s literature as it is of 'Tabloid' Photographic Chemicals. Time does not change nor custom wither their infinite variety and freshness. We do not know how many years have elapsed since this firm first issued its annual booklet advocating sound photographic technique in regard to time and temperature development and other processes, but they were certainly pioneers in the matter. Their advocacy of these sound methods continues, but every year they give us something fresh.

This year, under the title "Foresight in Photography," their booklet is particularly breezy. On the cover is a blue-toned photogravure reproduction of Commander Wild in the crow's nest of Sir E. Shackleton's *S.S. Quest*, and throughout the text pages the smack of the sea is continued as we read how modern scientific methods of navigation and photography follow similar methods of precaution as guides to the harbour of success.

For instance, "Development by Chart" is a happy title to the chapter on the time development, and the comparison of the nautical compass with the photographic calculator is no less apposite.

Among the illustrations is a particularly interesting and novel presentation of the effects of chromium intensification and of the possibility of subsequent modification by the use of reducers and other methods. We have never seen this point demonstrated before.

The booklet contains a classification of plates and films according to their development speeds, time tables for development and much other useful matter. Readers can obtain a copy gratis and post free by application to Burroughs Wellcome & Co., Post Box 290, Bombay, if they mention this journal.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints of the literary pages of the "*Gazette*" gratis, if asked for at the time of submitting their manuscripts.

REPRINTS OF THE ARTICLE CONCERNED (ONLY), IN PLACE OF REPRINTS OF THE WHOLE OF THE LITERARY MATTER OF THE ISSUE, CAN BE SUPPLIED ON PAYMENT IF ASKED FOR AT TIME WHEN ARTICLE IS SENT IN. BUT AS THESE HAVE TO BE MADE UP SEPARATELY, THEY ARE NECESSARILY DELAYED.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

VARIATIONS IN THE POTENCY OF DIGITALIS PREPARATIONS IN THE TROPICS.

By R. N. CHOPRA, M.A., M.D. (Cantab.),

MAJOR, I.M.S.,

Professor of Pharmacology, Calcutta School of Tropical Medicine;

S. C. BOSE, M.B. (Cal.), M.R.C.P., D.T.M. (London),
Physician in charge Cardiac Department, Carmichael Medical College Hospitals;

and

P. DE, M.B. (Cal.),

CAPT., LATE I.M.S.,

Assistant Professor of Pharmacology, Calcutta School of Tropical Medicine.

PRATT (1910) was one of the first to point out the inefficiency of some of the digitalis preparations on the market. Goodall (1912) examined a number of tinctures of digitalis over a period of three years and found great variations in their potency. Hatcher and Eggleston (1913) investigated the keeping properties of digitalis leaf and some of its preparations, on account of the prevalent idea among physicians that they undergo deterioration very rapidly. They employed mainly the "cat method" and in some instances the "one hour frog method" to estimate the activity of the specimens. They assayed, in this way, samples of leaves (ground and unground), tinctures and fluid extracts ranging from less than one to more than thirty years old. They came to the conclusion that commercial leaves of good quality, unless they were mouldy, showed little deterioration. Pharmacopoeal preparations containing 50 per cent. of alcohol according to them showed no greater deterioration than the leaves. Roth (1916) found by the "one hour frog method" large variations in the strengths of tinctures. Newcomb and Rogers (1918) laid much emphasis on the effects of temperature on the strength of various preparations and considered that even chilling below 40° F. for a short time decreased the potency of tinctures by an increase in the natural precipitation, which carried down some of the active principles of the drug.

Tate (1921) pointed out that tinctures of standard strength deteriorate in a warm climate like that of India owing to heat, and need to be frequently tested. He suggested that all the tinctures made from mixed Indian leaves and stored in the Government Medical Store Department should be tested once a year. Canby Robinson (1922) showed that in America tinctures kept in a hospital room in a five-gallon container, and which to begin with were of standard strength (1 c.c. = 1 cat unit), lost 50 per cent. of their efficiency at the end of one year. Brot

(1923) showed that digitalis lost 43 per cent. from heating in aqueous extract and 16 per cent. by treatment with alcohol.

It will thus be seen that though difference of opinion exists as regards the keeping properties of digitalis leaf and its preparations, most of the evidence goes to show that the strength of tinctures undergoes deterioration, especially if the temperature is high. Our attention was drawn to this as we found that the majority of our patients who were given tinctures of digitalis required a much larger quantity and a longer time to get under the digitalis effect than would have been necessary if the tinctures had had the potency of a standard tincture (1 c.c. = 1 cat unit). Eggleston has calculated that the average amount inducing full therapeutic effects within 36 to 48 hours in an adult man, who has not received digitalis previously, is about 1.5 gm. of the leaf or 15 c.c. of the tincture per 100 pounds of body weight; the tincture being given in divided doses at intervals of 4 to 6 hours. According to Mackenzie, 5 to 8 drams of tincture usually produce the desired effect. We tried tinctures of several makes and found that in every case a much larger amount of the tincture was required than that calculated according to the above formula. We therefore decided to carry out biological as well as chemical assays of a number of tinctures which we had used on patients in order to see whether the larger amounts required were due to deterioration of the potency of the tinctures, or to some other cause.

We selected the tinctures manufactured by one of the best and most reliable firms for our investigation.

Method of assay.—Our biological assays were carried out by Hatcher and Brody's "cat method." Two cats were used for each assay, and if the results varied largely the test was applied to a third cat for confirmation. Chloretone 0.2 gm. per kilo. body weight was administered intraperitoneally as an anæsthetic. The tinctures were diluted with 9 parts of physiological saline and the injections were made into the femoral vein. The average time occupied for injections was 60 to 90 minutes, the rate of injection being 1.0 c.c. of diluted tincture in 2½ to 3 minutes. In no instance was the combined method of finishing up the assay with ouabain used. Our chemical assays were done by Kundson and Dresbach's improved method, and we are very grateful to Mr. N. Ghosh for the trouble he has taken in making these assays.

Clinical trials.—In table I we have put down the results of use of tinctures of digitalis, manufactured by one of the best firms, in a series of cases. Each patient was given a four ounce sealed bottle of standardised tincture of digitalis, the latest stock available. He kept the bottle tightly corked and in a cool and dark place. Each dose was accurately measured out, diluted with water, and taken on an empty stomach. No

TABLE I.

No.	Race, age and weight of the patient.	Cardiac and other lesions present.	Amount in drs. necessary to get the patient under digitalis.	No. of days of digitalis administration to get the patient under.	Amount of standard tincture (1 c.c. = 1 cat unit) required for digitalis effect.	Date of manufacture of the tincture.	Date of use of tincture.	REMARKS.
1	European 41 years 168 pounds.	Mitral stenosis hypertrophy, auricular fibrillation, tachycardia.	18 drs. + 1/100 gr. of strophanthin (Merck) to reduce pulse from 140 to 85 per minute.	13 days. Dose 80 minims daily.	7.1 drs.	May 1923.	Aug. 1923.	
2	Hindu male 70 years 126 pounds.	Granular kidney, arterio-sclerosis, myocardial degeneration, tachycardia.	14 drs. to reduce pulse from 108 to 70 per minute.	15 days. Dose 60 minims daily.	5.4 drs.	Oct. 1923.	Jan. 1924.	
3	Hindu female 14 years 80 pounds.	Aortic regurgitation, mitral stenosis, rheumatic myocarditis.	14 drs. to reduce pulse from 140 to 90 per minute.	16 days. Dose 60 minims daily.	3.4 drs.	Oct. 1923.	Feb. 1924.	
4	Hindu male 62 years 140 pounds.	Granular kidney, arterio-sclerosis, myocardial degeneration, tachycardia.	14 drs. to reduce pulse from 110 to 80 per minute.	12 days. Dose 90 minims daily.	6.0 drs.	Nov. 1923.	Feb. 1924.	
5	Hindu female 28 years 100 pounds.	Aortic regurgitation, mitral stenosis, rheumatic myocarditis, auricular fibrillation.	15 drs. + 1/200 gr. of strophanthin (Merck) to reduce pulse from 160 to 80 per minute.	13 days. Dose 90 minims daily.	4.3 drs.	Nov. 1923.	Jan. 1924.	
6	Hindu female 78 years 140 pounds.	Granular kidney, arterio-sclerosis, myocardial degeneration, auricular fibrillation.	12 drs. to reduce pulse from 160 to 90 per minute.	10 days. Dose 120 minims daily.	6.0 drs.	Nov. 1923.	Jan. 1924.	
7	Hindu male 59 years 140 pounds.	Angina pectoris, tachycardia, myocardial degeneration, arterio-sclerosis.	29 drs. to reduce pulse from 100 to 70 per minute.	26 days. Dose 120 minims daily.	6.0 drs.	Jan. 1924.	July 1924.	
8	Hindu female 45 years 130 pounds.	Tachycardia, emphysema, diabetes, heart failure.	14 drs. to reduce pulse from 136 to 95 per minute.	16 days. Dose 60 minims daily.	5.6 drs.	Jan. 1924.	July 1924.	
9	Hindu male 53 years 125 pounds.	Mitral stenosis, rheumatic myocarditis, tachycardia.	21 drs. to reduce pulse from 100 to 60 per minute.	30 days. Dose 60 minims daily.	5.3 drs.	Apr. 1924.	Aug. 1924.	
10	Hindu male 52 years 115 pounds.	Granular kidney, myocardial degeneration, tachycardia.	10 drs. to reduce pulse from 112 to 88 per minute.	9 days. Dose 120 minims daily.	5.0 drs.	Apr. 1924.	Sept. 1924.	
11	Hindu male 52 years 140 pounds.	Mitral stenosis, auricular fibrillation, rheumatic myocarditis.	17 drs. 1/200 gr. of strophanthin (Merck), 2 injections, and 60 c.c. of digitipuratum to reduce pulse from 118 to 102 per minute.	10 days. Dose 6 c.c. daily.	10.0 drs.	Apr. 1924.	Aug. 1924.	Digitipuratum had to be given up and tincture digitalis (Parke Davis) given. Total 9 drs. + 1/200 gr. of strophanthin to reduce heart rate from 102 to 70 in 5 days. (60 c.c. fluid digitipuratum = 45 grs. of powdered leaf.)

TABLE I.—(Concl'd.)

No.	Race, age and weight of the patient.	Cardiac and other lesions present.	Amount in drs. necessary to get the patient under digitalis.	No. of days of digitalis administration to get the patient under.	Amount of standard tincture (1 c.c.=1 cat unit) required for digitalis effect.	Date of manufacture of the tincture.	Date of use of tincture.	REMARKS.
12	Hindu male 45 years 150 pounds.	Aortic dilatation, syphilitic myocarditis, tachycardia.	18 drs. of tinct. digitalis + 1/200 gr. strophanthin (Merck) to reduce pulse to 85 per minute.	20 days. Dose 60 minims daily.	6.4 drs.	Apr. 1924.	Oct. 1924.	
13	Hindu male 50 years 150 pounds.	Aortic dilatation, syphilitic aortitis.	4 drs. of tinct. digitalis prepared in Chemical Laboratory of School of Tropical Medicine to reduce pulse from 100 to 80 per minute.	4 days.	6.4 drs.	
14	Hindu male 38 years 160 pounds.	Myocardial degeneration, granular kidney.	9 drs. of tinct. digitalis prepared in Chemical Laboratory of School of Tropical Medicine to reduce pulse from 120 to 90 per minute.	9 days.	6.8 drs.	
15	Hindu female 17 years 120 pounds.	Rheumatic myocarditis, mitral stenosis, aortic regurgitation, tachycardia.	10 drs. to reduce pulse from 140 to 90 per minute.	12 days.	5.1 drs.	July 1924.	Nov. 1924.	

other drugs were taken along with it. It will be observed that although adequate doses had been given, in no case was the complete effect brought about by the amount calculated to be necessary if the tincture had been of standard potency. In the majority of cases double the amount was necessary and was required over a longer period. In cases Nos. 1 and 5 intravenous injections of strophanthin were used in addition. In case No. 11 digitipuratum was tried and here also a larger dose was required and strophanthin had to be given in addition and even then the heart was only imperfectly under. It may be mentioned here that the "digitalis effect" is produced when signs of minor digitalis intoxication, such as nausea and vomiting, marked anorexia, reduction of the heart rate below 80, appearance of occasional premature beats, coupling of the beats, and diminished diuresis occur. Directly one or other of these events occurs, the drug is stopped or greatly reduced. It is worthy of note that the stage of optimum therapeutic effect usually merges into that of minor digitalis intoxication.

Discussion on Table I.—The doses of tinctures used in this series were 20 to 30 minims of the tincture three times daily and the average period necessary to get the patient under digitalis was in most cases 12 days, and in some cases considerably longer. From this it can be imagined how long it would take to get a patient under

digitalis if the doses ordinarily prescribed by medical practitioners in India—i.e., 5 to 10 minims three times a day—were given. It has been calculated that an average healthy adult destroys about 22 minims of tincture in 24 hours and this quantity passes out of the body without producing any therapeutic effect. The balance accumulates in the heart muscle till sufficient concentration is reached to produce its effect. At this rate it would take a month or even longer, and the quantity of the tincture required to be used would be considerably more because proportionately larger amounts will be destroyed by the body as its use is spread over a longer period. Medical practitioners somehow seem to be afraid of giving large doses of tincture for the reason that it is supposed to cause poisoning. It has been shown that poisoning with digitalis is very rare, as nausea and vomiting supervene quickly with the advent of toxic dosage or even before that is reached. As much as one minim of the ordinary tincture per pound weight (two drachms for a man weighing 120 pounds) can be given in a single dose if quick therapeutic effects are desired, without producing untoward symptoms, provided certain precautions are followed. After the therapeutic effect is produced the dose can be reduced to 10 minims three times a day to keep the heart under digitalis effects. In cases Nos. 13 and 14 a tincture prepared in our laboratory from fresh leaf grown in Kashmere

was administered. The dose required with this preparation was nearly the same as with a tincture of standard strength.

Biological and Chemical Assays.—In Table II, we have put down details of the biological assay of the tinctures used in Table I, and also the results of chemical assays of a number of these tinctures. It will be observed that when tested by the "cat method" the potency of the tinctures

carefully filtered to prevent obstruction of the coronary artery with emboli, are very toxic to cats when given intravenously and produce sudden death with much smaller doses than the standard tincture. If the assay is done with the guinea-pig or frog method in which the tinctures are injected subcutaneously, they do not show this increased toxicity, but a great reduction in their potency is evident. We have noticed that

TABLE II.

showed a reduction in most cases of from 20 to 40 per cent.; the chemical method of assay shows a much larger reduction.

Discussion on Table II.—In the assay of tinctures Nos. 1, 2 and 3 a much smaller quantity was required to produce lethal effects than would have been necessary with the ordinary standard tincture. Most of the good tinctures when they are diluted with 9 parts of physiological saline give an opalescent light-green colour. Some of the tinctures, however, form a blackish solution on dilution which is not uniformly opalescent, but contains particles of what looks like precipitated matter. These tinctures, though they were

this change occurs in the tinctures when they have been stored for some time, especially during the hot weather months. In some of the tinctures made from Indian leaves which we assayed a few years ago and which had been lying in store for some time during the hot weather we found that this change had occurred. What chemical changes take place which increase the toxicity we have not been able to determine. The freshly prepared tinctures from the Indian leaf in some cases were slightly darkish in colour on dilution as compared with imported tinctures, but were uniformly opalescent. It may be pointed out that the biological assay tells us how much

of the active principles of digitalis are lethal to the animal. It is by no means certain that the active principles that produce death are the glucosides which cause therapeutic effects, though in fresh tinctures at any rate there is a distinct relationship between the two (see Tables I and II: clinical trials and assays Nos. 13 and 14 of fresh tinctures made from Kashmere leaf). It is quite obvious from a perusal of the tables that samples of tinctures which in small doses are quite strong enough to be lethal to cats when given intravenously, are perfectly useless when administered by the mouth to man. They are probably decomposed in the alimentary tract and rendered inert and innocuous. From the observations which we have made with a number of tinctures in Calcutta we have come to the conclusion that a correctly assayed and standardised tincture of digitalis passes through the following stages with age and high temperature:—

(1) At first it becomes less potent and less toxic to animals, i.e., instead of the M. L. D. for a cat being 1 c.c. of the tincture per kilo. body weight it becomes 2 to 2.5 c.c.

(2) As further changes occur, certain products are formed and the tincture becomes more toxic to animals when given intravenously. The M. L. D. for a cat then becomes 1 c.c. per kilo. body weight or less, though its therapeutic efficiency is considerably reduced.

It is quite evident from the data which we have accumulated in the tables that no single method of assay, either biological or chemical, can be relied upon by itself as a test for the potency of a tincture which has been in a tropical climate for some time.

Naked eye changes of colour and turbidity give information and should always be observed. It would appear that the only infallible way of judging the potency of a tincture in the tropics is the clinical method, i.e., testing the tincture on diseased hearts in man. A tincture that can digitalize a patient with auricular fibrillation at an average dose of 15 c.c. of tincture per 100 pounds body weight is certainly the most dependable preparation, whether or not the biological test is satisfied.

Summary and Conclusions.

(1) Clinical observations as well as biological and chemical assays of tincture of digitalis show that it undergoes deterioration rapidly in a tropical climate such as that of India.

(2) This deterioration cannot be accurately determined by any single method in the laboratory, such as Hatcher's "cat method"; the "frog method"; or Kundson and Dresbach's chemical method.

(3) Clinical tests give the most reliable information. The average dose of 15 c.c. (or 4½ drachms) of the tincture per 100 pounds of body weight required to get the patient under digitalis effect in 36 to 48 hours is considerably increased after the tincture has been in the tropics even for a short time.

(4) Deterioration is due to some change in the digitalis glucosides, the nature of which has not yet been determined. The tinctures on dilution become darkish in colour, unlike good tinctures which are light green and uniformly opalescent. Such tinctures are more toxic to cats when given intravenously, but a considerable weakening in the therapeutic efficacy is evident.

(5) The dosage of tincture of digitalis generally employed by medical practitioners in India (i.e., 5 to 10 minims three times a day) is far too small to get the patient under the digitalis effect within a reasonable period, (3 to 4 days).

(6) With tinctures of standard strength doses of at least 20 to 30 minims three times a day should be given. If rapid effects are desired in urgent cases these may be increased from 45 to 60 minims till the amount calculated by Eggleston's method is given.

AN INVESTIGATION INTO THE ORIGIN OF CHOLERA EPIDEMICS IN THE JHERIA COAL-FIELDS.

By G. C. MAITRA,

CAPTAIN, I.M.S.,

Research Worker, Calcutta School of Tropical Medicine.
(Mining Association Endowment.)

OCCASIONAL epidemics of a disease, which is clinically cholera, have been known in the coal-fields for a long time, and have occupied a conspicuous place in the statistical reports of

the Mines' Board of Health. Such cases are returned almost throughout the year, but high case incidence and high mortality are noticeable only at certain seasons, (*vide* chart No. 1).

CHART.

Detailed consideration of the chart:—The monthly figures for cholera with corresponding mortality rates per 100 seizures have been depicted for 5 consecutive years from 1919 to 1923. The vertical columns at the bottom represent the mortality rate, and the curve in black lines the number of cases reported both from the collieries and rural areas in the mining settlement. A close examination of the chart will shew that while the maximum mortality rate corresponds closely to the height of the outbreak in the real epidemic year of 1919, it is erratic for the following four consecutive years. This is no doubt due to the inclusion of both cholera and cholera-like diseases in the monthly figures. Chance variations and faulty reporting detract from the value of the figures when the number of cases is small.

Since the great epidemic of cholera of 1919 with about 2,500 deaths out of 4,400 seizures, no outbreak of similar magnitude has been known for the last five years. But small annual epidemics occur even now in the coal-fields, and when such an event happens in a colliery it causes a great panic among the ignorant labourers, leading to their wholesale desertion and temporary closure of the affected colliery. As the question was so important from the industrial point of view, it was thought desirable to investigate it, and a small laboratory was opened at the Mudidi Hospital for facilitating our work. The accommodation for this purpose was obtained through the courtesy of Mr. Leach, Chief Mining Engineer of Messrs. Bird & Co., Calcutta.

The investigation was conducted partly out-of-doors in obtaining detailed histories of all cases reported as cholera through the office

of the Chief Sanitary Officer and in collecting blood and dejecta of such cases when available.

The work indoors consisted mainly in examining the fæces and blood of cases suffering or convalescent from suspected cholera and in routine examinations to detect carriers. Water samples from various sources were also examined to ascertain their connection with the sporadic or epidemic outbursts of the disease.

From the beginning of March practically to the end of July 1923, 250 cases were returned as cholera by the Health Office, Dhanbad,—the definition of cholera for such purpose being¹ "Every case of sickness accompanied by vomiting and diarrhoea shall be considered to be a suspected case of cholera." Of these I had the opportunity of investigating 45 cases, many of them in the acute condition. In Table No. I an abstract of the results of bacteriological examination of the fæces and blood of some of these cases is given. Along with the observations on acute cases, the fæces of 980 healthy persons were examined to detect cholera carriers among them, but no vibrios of any description were found, except in one case, where they were of non-agglutinating nature.

TABLE I.

Total No. of cases examined.	Result of examination of stool for cholera V.		No. of blood samples examined for Widal.	Reaction against		REMARKS.
	Microscopical.	Bacteriological.		V. Cholera.	B. Dys. Shiga.	
21	Nil.	Nil.	12	* Nil	Positive 5.	Agglutination at 1 in 20 and above was considered positive against Shiga's bacillus.

* None reacted at 1 in 40 and above at the end of a week from the onset of the disease.

From the preceding table it is evident that in no case could cholera vibrios be isolated, and in no instance did the blood of a convalescent react against cholera. The apparent conclusion, therefore, is that the cases in the above series were not caused by the classical Koch's vibrio.

As regards the distribution of these cases, no evidence of grouping of any sort was obtained. As a rule they were very much scattered, often miles apart from one another, and when there were multiple cases in a colliery or village no association between individual cases could be established. Absence of multiple infection in the same household was, indeed, a feature of this group of cases.

Clinically they resembled cholera and were of moderate severity. Apparently desperate cases responded remarkably well under kaolin treatment alone. Consequently the death rate was low, and there was little opportunity for post-mortem examination to study the nature of the pathological lesions. In one case, however, a partial autopsy was done immediately after death, and the lesions in the large intestine appeared to be a uniform congestion of the mucosa with points of sub-mucous hæmorrhage. The gall bladder was distended with liquid bile. The contents of the large intestine and gall bladder were negative both for cholera and dysenteric organisms. The intestinal exudate, fixed and examined fresh, showed a great preponderance of epithelial cells. They were mostly of columnar type with clumps of short rod shaped bacilli between them. The cellular elements in this respect simulated the picture of true cholera except that in the latter case the cells when stained do not come out so sharply and the field is usually found teeming with vibrios, *vide* Plate No. I where the two appearances have been depicted for comparison.

What are these cases then? The absence of comma vibrios, both in the smears and cultures of stools of acute cases, and the absence of multiple cases in the same household where the inmates do not observe the rudiments of personal sanitation, are points against cholera. The results of blood examinations in a few instances furnish some evidence of their being acute cases of Shiga infection and such cases have been mentioned by Rogers,² Cunningham,³ and Smith.⁴ But the absence of positive Shiga bacillus findings in cultures from clinically acute cases, even when the faecal specimens were obtained under ideal conditions and plated within an hour after they had been passed, raises a reasonable doubt as to the real nature of this group of cases. Hence the whole question has been left open for further investigation when opportunity presents itself in future.

Towards the end of July 1923, 11 cases were reported in quick succession from a small village on the Grand Trunk Road, about 8 miles from Dhanbad. The camp laboratory was shifted to Gobindpore within two miles of the affected village, and the epidemic was fully investigated both clinically and bacteriologically from there. Altogether 18 seizures with 8 deaths occurred in this epidemic. By the time the observation centre was opened, 7 cases had already died. So the materials from the remaining 11 cases were examined bacteriologically and genuine cholera vibrios were recovered from 8 of them. The stools of 3 convalescents were culturally negative for cholera vibrios, but their blood re-

cholera at the end of the second week after the onset of the disease.

PLATE I.

(1) Microphotograph of a stained film of cholera stool.

(2) Microphotograph of a stained film of the stool of a patient with suspected cholera, who died in the Mudidih Hospital and on whose body a partial autopsy was done.

The sources of drinking water and batches of flies from the houses were examined as probable agents for spreading cholera, but nothing incriminating was found.

The history of the origin of the epidemic is interesting. One Santokh Das Babaji, a Hindu ascetic, had a fixed worshipping place in village Nero where the epidemic started. He had gone to Puri on pilgrimage during the car festival. Within a couple of days after his return from Puri he developed cholera and was nursed mostly by his disciples of the sect. Practically all the people who

had nursed Santokh Das, or had been in close association with him during his illness, developed cholera sooner or later, and carried the disease to their respective households. Three families were particularly affected in this epidemic, and there were in all 16 cases among them with 7 deaths.

The local sanitary authorities had in the meantime mobilized their personnel and adopted vigorous preventive measures which stopped the further progress of the disease. Two isolated cases subsequently took place in the adjoining village, but the infection was never allowed to spread, and the epidemic was controlled and completely stopped by the middle of August 1923.

Almost about the same time when the Nero epidemic was raging, a small and more or less localized outbreak was reported from Kirkend bazar, a place of commercial and industrial importance and situated midway between Jheria and Katrasgarh on the Jheria-Katras road. A group of 5 cases, more or less intimately associated with one another, was reported in 3 days. From the faeces of 2 of these cholera vibrios were isolated, the remaining 3 having died before the investigation could be taken up.

The 1st case in this group occurred in a family 5 days after their return from Baidyanath where they had gone on pilgrimage. Cholera vibrios were obtained in pure culture from the stool of this case. The next 2 cases died so quickly that materials for examination could not be obtained from them. There was a positive culture from the 4th case, but the 5th case also died before examination.

The Kirkend bazar outbreak was followed a few days later by a rather severe outburst of the disease in the Jamadoba Colliery belonging to Messrs. Tata & Sons. The first victim on this occasion was attacked on the day after the Mohurram festival was over, after his return from the usual gathering which takes place on the occasion of the immersion of the *tazias*. A number of cases followed, and from the materials obtained from 2 of these, cholera vibrios were isolated. Thus the epidemic in the Jamadoba Colliery was due to Koch's vibrio, and it is interesting to note that it closely followed the Kirkend bazar outbreak when the disease had already established itself in the centre of the Jheria coal-fields.

It is evident from last year's observations that cholera in the Jheria coal-fields is imported from pilgrim centres; this is probably the usual course of events from year to year.

Taking cholera to be an imported disease in the coal-fields, the preventive measures ought to be considered from two points of view:—

(1) Prevention of importation of the disease from pilgrim centres.

(2) Prevention of the spread of the disease when it has already established itself.

1. Prevention of importation of the disease:—

This is obviously impracticable, for not only convalescent carriers, but apparently healthy men who have imbibed the infection, and are in the incubation period of the disease pass from one part of the country to the other. Such sources of infection are more dangerous than others, as they are more likely to evade the most careful vigilance.

2. Prevention of spread of the disease when it has already established itself:—

This is more important and applicable to the local conditions. The machinery already exists in the Jheria coal-fields for this purpose, but there is ample scope for improvement. Notification of infectious diseases is compulsory in the coal-fields within 3 hours, but this is not strictly observed. Non-compliance with this standing order is due not so much to slackness on the part of the individual colliery authorities as to the ignorance and superstitious belief of the people themselves. Coercive measures are not likely to improve the present attitude. Persuasive methods on the other hand, by giving substantial rewards for early notification of cholera cases, are calculated to be more successful. In the case of individual collieries, labour contractors ought to take more interest in the health of the miners. At present these people, with very few honourable exceptions, are mainly concerned with the profits of the middle man and many of them make their fortunes in this way. There is no reason why they should not be made responsible for early notification of cholera cases occurring among their men. Next, methods of isolation and disinfection ought to be strictly applicable to genuine cholera with Koch's vibrio as the causative agent. It has been already recorded in the previous pages that a cholera-like disease with indefinite etiology is common in the coal-fields. Such possibilities ought to be excluded before recommending isolation (an unpopular step) and elaborate and expensive disinfection. And as correct discrimination between the two can only be done by careful bacteriological examination and clinical observation, a competent bacteriologist with a small staff and a mobile laboratory are necessary for the coal-fields.

Specific immunisation of susceptibles by subcutaneous inoculations is not likely to be popular with the labouring class, and its practicability cannot be assessed at present without further observations in India. Under suitable conditions it should be tried. Vaccination by the oral route is a possibility and an investigation into the value of this in intestinal infections is about to be carried out

in connection with this research; oral vaccination has apparently given good results in Russia and elsewhere, it is harmless and is likely to be acceptable to the people concerned. It should be tried, together with the preventive mixture found so useful by Dr. Tomb.²

SUMMARY.

1. A cholera-like disease with indefinite etiology exists in the coal-fields. Further investigation will be made of this important condition when opportunity offers.

2. This disease appears to be of low infectivity and was never seen to assume epidemic proportions nor to give rise to multiple cases in the same family.

3. Cholera epidemics due to Koch's vibrio were imported last year into the coal-fields from the pilgrim centres of Puri and Baidyanath.

4. Elaborate and costly disinfection measures are only justifiable when the outbreak is due to the genuine cholera vibrio, and as this can only be ascertained by careful bacteriological examination, a competent bacteriologist and epidemiologist with a mobile laboratory is a necessity for the coal-fields.

5. In the absence of a competent bacteriologist, all cases which have the clinical features of cholera must, of course, be dealt with as if they were true cholera.

6. The value of specific immunisation against cholera, both subcutaneously and by the mouth, cannot yet be assessed without further extensive trial, side by side with other methods of preventive medication.

7. The scientific method of prevention is not necessarily the best; the prejudices of the affected population and the local conditions must be taken into account.

THE TREATMENT OF ASTHMA.

By HUGH W. ACTON,

MAJOR, I.M.S.,

Professor of Bacteriology and Pathology.

and

R. N. CHOPRA, M.A., M.D. (Cantab.),

MAJOR, I.M.S.,

Professor of Pharmacology, School of Tropical Medicine and Hygiene, Calcutta.

Introduction.—In medicine there were axioms taught to us during our student days:

and one of them was that "if there were several drugs for the cure of a single disease, there was no real cure." The converse argument can also hold good, viz., if there are several drugs that really help in the cure of a disease, we probably do not know how and when to use them. That such a state of affairs actually exists in the treatment of asthma we will proceed to show in this paper. In 1923 we pointed out that asthma was not a disease, any more than dropsy or jaundice, but that it was a symptom-complex caused by various bases probably all derived from the proteins, some volatile and others non-volatile. As these bases all act through cell membranes (Acton, 1924), it was highly improbable that they are proteins with large indiffusible molecules, but are diffusible protein bases, e.g., polypeptides, etc. Moreover, they are not simple bases like methylamine, etc., as these have a very low toxicity, but are of a more complicated structure like adrenaline and tyramine, or tertiary nitrogen bases like the betaines and alkaloids. They are therefore intermediary decomposition products of proteins of a complex structure which are diffusible and toxic to animals.

The next point we had to consider was the question of individual susceptibility (Acton and Chopra, 1924), and here we found that it was largely correlated with the adrenal and thyroid functions of the animal. Again, when considering species variation we observed that it was associated with vagal or sympathetic predominance. In a more recent work on the subject, Bose and Acton (1924) in a preliminary paper have shown that the action of a base such as insulin is closely correlated with the colour of the animal, viz., albino rabbits are not sensitive, but black rabbits are very sensitive to the effects of insulin.

We therefore see that in these variations there are three groups in the different species of animals, as well as individual variations in the species:—

(a) Animals with high endocrine functions; e.g., the *Macacus rhesus* monkey and the albino rabbit; these animals resist the action of these bases, except when they cause a rise of blood pressure.

(b) Animals with moderate endocrine functions, e.g., the cat usually, and the brown Belgian hare rabbit; in whom the action of these bases is moderate in intensity.

(c) Animals with a low endocrine function, and these can be further subdivided into:—

(c₁) Animals with a low sympathetic endocrine function, sympathetic predominance; e.g., black rabbits and cats.

(c₂) Animals with low parasympathetic endocrine functions, parasympathetic nervous predominance, as shown by the high blood sugar, e.g., dogs.

The animals in the last group (c) fall into the category of sensitive individuals with sympathetic or vagal predominance, and this is correlated with variations in the species and colouration in the individuals. These variations are in general terms of susceptibility as regards race and colour. When we consider individual variations in the species, given favourable conditions, i.e., animals with a low adrenalin or insulin content, there is still another factor to consider,—the rate of diffusibility of the substance through the cell membrane.

Our recent experiments on the concentration of quinine and quinidine in the circulating blood—now in press—make this point quite clear. The enhanced toxicity of quinidine is due to its more rapid diffusion through the mucous membrane of the intestine, and to its greater adsorption by the tissue cells, and both these factors vary in the individuals under test. From a morphological standpoint we are led to the conclusion that both sympathetic (e.g.—trematodes, etc.) and parasympathetic nervous systems have a dual control, containing relaxor and constrictor fibres in each

In sympathetic predominance, owing to the deficiency in the amount of adrenalin, the cell permeability is increased and hence the pressor bases that stimulate the sympathetic are more diffusible, attain a greater concentration in the cell or at the nerve terminals and hence act more powerfully. In vagal predominance, owing to the deficiency in the amount of parasympathetic hormones, e.g., as shown by high blood sugar, the permeability is increased, and hence tertiary nitrogen bases that stimulate the vagus are more diffusible and so cause marked symptoms.

The causes of bronchial spasm and turgescence.—The first essential in the rational treatment of this symptom-complex is to find out the cause. In these persons we are generally dealing with a lower adrenal content in the blood than the normal, or with a lower insulin content. We can therefore classify these conditions of susceptibility into two main classes:—

(a) *Sympathetic predominance.*—In such individuals there is often a history of hereditary susceptibility, and the adrenal content is low. The causes of this condition may be due to:—

(A) *The animal group.*—Emanations from various animals, as well as the pollens of various plants may cause bronchial spasm. In the former these substances are almost certainly volatile bases, and in the latter are soluble diffusible bases that enter through the conjunctival or mucous membrane. In India; hay fever is very rarely seen, except in hill stations when it is due to the pollen of the

deodār. These attacks may be of nightly occurrence if the animal lives in the house; irregular, as when the patient visits a friend in the house or is benefited by a change of residence; seasonal, with pollens, or by using say an eider-down quilt in the winter. We can quote a case where we found a lady to be very sensitive to eider-down, and advised her to present her quilt to her mother. After following our advice she has been practically free for two years. From the history and the dermal tests these cases can now be readily diagnosed in the laboratory. The obvious thing to do by way of treatment is to avoid the particular animal or pollen if possible, or to desensitise the patient by injections of the particular poison (see the *Indian Medical Gazette* for May, 1924, paper by Dr. A. R. J. Douglas).

This case was diagnosed by us as being sensitive to the horse and cat by the epidermal tests. She could live perfectly free from asthma in Ceylon, because there is practically no horse traffic there, and bullock carts, rickshaws and motors are the usual methods of transport. In Calcutta her lungs were full of expiratory rhonchi but there were no definite asthmatic attacks, as there is only a fair amount of horse traffic on the streets. In the district where her husband lived there was practically nothing but horse transport, and day and night she was subject to asthmatic attacks. Six months after desensitisation, she came down to a hotel and slept next to a lady who kept a number of cats and she got another attack. As we have not heard from her since, we conclude she must be still free from asthma.

(B) *The food group* can in a similar way lead to a daily attack, if the asthma is due to some common food; irregular, if it happens to be a food which is only taken occasionally; seasonal, when the article of diet has a seasonal variation, e.g., mango, fish, etc. Occasionally this condition may be associated with disease in the bowel (Acton and Knowles 1924), as in *Entamoeba histolytica* carriers, when the digestion of the proteins is not properly carried out by crepsin. Here again the avoidance of the particular food is indicated, if it is possible; otherwise the indication is to increase the resistance of the patient by endocrine administration; by injections of arsenic (soamin); or the treatment of the bowel condition. In this group the eosinophile count is always very high.

(b) *Vagal predominance.*—In these individuals there is often no history of heredity, as the condition is generally due to the various bacterial infections of the respiratory or other parasympathetic areas. The adrenal content is often fairly high, but these individuals are very sensitive to bases like pilocarpine. The causes of this condition may be due to:—

(B₁) *Some irritation in the area supplied by the vagus nerve.*—Here the mental factor is of great importance, the so-called nervous asthma. The case that is often cited in support of the nervous theory is the occurrence of asthma in a lady who was sensitive to rose pollen, and who used to get asthma after smelling an artificial rose. The irritation in this area may be due to such trivial causes as vibrissæ at the nasal orifice. Thus it may be due to various nasal and pharyngeal defects; bronchitis, and development of sensitiveness to various causative micro-organisms; after pneumonia and then due to the pneumo-bacillus or pneumococcus. More rarely it is seen with pulmonary tuberculosis, but very commonly indeed with enlarged bronchial glands of tubercular origin. The obvious thing to do is to correct any nasal defect, to remove the irritation, and so render the patient less liable to attacks of nasal catarrh and its extension into the bronchi. Also to increase the general resistance, by tuberculin, or by vaccines made from the causative organisms; as well as by general treatment, fresh air and giving plenty of live animal fats and proteids, as these increase the endocrine defence mechanism.

(B₂) *Stasis of decomposition products in the blood*, such as carbon dioxide, etc., which occurs in cardiac asthma and in the asthma seen in a failing renal heart. In true renal asthma the bases act more powerfully on the sympathetic. In all these conditions of stasis, unless it can be overcome by the ordinary treatment of cardiac tonics, e.g., digitalis, nux vomica, strychnine, or by diuretics and purgatives, only temporary relief can be obtained by the drugs that act centrally, e.g., morphia, or through the vagus as with the nitrites, etc.

The majority of cases, however, are not simple cases of predominance of the vagus or sympathetic nervous system, but in 70 per cent. of the cases they are mixed in character. Thus in a case of sensitiveness to a particular food, the repeated attacks of asthma render such a susceptible person more liable to attacks of bronchitis, and this in its turn leads to the development of sensitiveness towards the causative bacteria. Again, the irritation by vagotonia produces asthma and ill health, then perhaps a sensitiveness develops towards some foodstuff. Nasal defects predispose to nasal catarrh, and this in turn to susceptibility towards the various causative organisms.

The treatment of asthma.—Having discussed fully the various causes of this symptom-complex, we are now in a better position to understand its rational treatment by the various drugs enumerated in the textbooks as being useful in this condition. We

can best describe them under the following headings:—

(a) *Treatment during the stage of attack.*—The drugs that act through the central inhibitory centre of the vagus; these are all useful, viz., ether, chloroform, chloral hydrate and morphia, but they act without removing the cause. Their use is only justified in conditions like cardiac failure due to heart disease or renal disease, when the toxic stasis cannot be removed by other drugs, and the patient's days are numbered. The use of these drugs is extremely dangerous owing to the formation of drug habits, and they had better be avoided altogether, because we are not removing the cause of the symptoms, but merely using them as a placebo to relieve symptoms.

(A₁) *In sympathetic predominance* the action of adrenalin is best seen, for it markedly dilates the bronchial muscle with practically no action on the heart. Doses of two to five minims injected intramuscularly or intravenously are well tolerated and the effects are almost instantaneous, and owing to its inhibitory action on these bases the effect lasts a long time. In this category one could mention lobelia, which has an action like nicotine, and paralyses the sympathetic, so it is sometimes useful when smoked as a cigarette. Another drug that has a limited use is tyramine. Adrenalin fulfills our requirements, as tyramine, although its effects on respiration are more prolonged than those of adrenalin, does not inhibit the action of the bases.

(A₂) *In vagal predominance* on the other hand, adrenalin when injected intramuscularly has only a slight and evanescent effect in overcoming the bronchial constriction caused by these bases acting on the vagus. Doses as large as five minims of adrenalin hydrochloride often cause a very high rise of blood pressure and irregular action of the heart. For these reasons, vagotonic individuals generally object to injections of adrenalin. The drugs that are preferred by them during the acute attacks are the phenacetin group which act on the algesic centres and cause vaso-dilatation of the vessels, thus relieving turgescence. The nitrites, e.g., amyl nitrite, nitroglycerine and sodium nitrite, give great relief in the failing renal heart and in cardiac failure. Lastly, the value of atropine and cocaine when given as a fine spray is very great, for both paralyse the vagus and lessen bronchial secretion. The same result is brought about to a lesser degree by inhaling the fumes of stramonium as cigarettes or when these drugs are burnt in an open pan.

As vagotonia is more common than sympathetic predominance, it is for this reason that the various so-called proprietary asthma cures, viz., the preparations of stramonium and nitre as cigarettes or inhalations, the

inhalation of amyl nitrite, the fine spray of atropine and cocaine, hold their sway over these patients and find a large and continuous sale. As long as the exciting cause is not removed, all these drugs are only methods of treating the condition symptomatically.

(b) *Symptomatic treatment between the attacks.*—This is often advisable in order to give relief during carrying out of the necessary examinations for finding the cause, or when increasing the resistance of the individual.

(B₁) *In sympathetic predominance* the difficulty is usually owing to the viscosity of the sputum, for the cedema of the mucous membrane hinders the secretion of the mucous glands and so expectorants, especially potassium iodide in small doses (grs. iii) and others, relieve this condition. Lobelia is given as tinct. lobelia ætheris m. xv., as lobeline paralyzes the sympathetic, like nicotine. In such cases the following prescription can be given:—

Potass. iodide	grs. iii.
Tinct. lobelia ætheris	m.x. vel. xv.
Sodii bicarbonas	grs. x.
Sodii chlor.	grs. x.
Sp. chloroformi	m.x.
Aq. anethi	ad. oz. i.
t.d.s. p.c.			

(B₂) *In vagal predominance* there is generally increased expectoration, and the belladonna group in full doses diminish secretion and paralyse the nerve endings of the vagus. With belladonna we can combine bromides, and in such cases the following prescription can be given:—

Pot. bromide	grs. v vel. x.
Borax	grs. ii.
Tinct. belladonnæ	m. iii to v.*
or			
Ext. Kuth radix	dr. i.
Sp. chloroform	m.x.
Aqua	ad. oz. i.
t.d.s. p.c.			

* These cases are often sensitive to belladonna.

Chopra 1924 has found the extract of Kut root to be very efficacious in these cases.

In a few cases associated with tubercular or streptothrix cavitation of the lung, benzyl benzoate 15 mins. as a 20 per cent. solution in alcohol has given good results in preventing these spasms.

(c) *The cure of asthma, or the prevention of attacks.*—The first essential thing to do is to find and remove the cause, and failing that to increase the defence mechanism.

(C₁) *Remove the cause.*—In the sympathetic group this is more easily done, for the animal or food responsible can usually be detected by the dermal tests. Curious mistakes have occurred in our experience; one patient we found was sensitive to wheat, so all bread was cut off from his diet, yet the asthmatic attacks continued; it was not until we more carefully

investigated his diet that we elicited the fact that in the hospital diet *suji*, a wheat preparation, was also given to the patients. In a second case, the patient was found sensitive to *rohu* and *hilsa* fish; he was given no fish in his diet, but was ordered meat curry and rice. Still the asthma continued, and on careful watching the nurse found that he used to ask the cook to help him to a spoonful of the gravy of the fish curry because the meat curry was dry. In a third, the patient was insensitive to milk proteins: in this case the disease was urticaria and he invariably got his rash between 2 to 4 p.m. These bases take about 6 hours to get into the circulation and about the incriminating meal was thought to be breakfast. Here we found that at breakfast he had curdled milk every morning and when tested with it gave a very marked reaction by the dermal test, but was insensitive to fresh milk and was cured by eliminating this article from his diet. With a dermal reaction to many food substances we found these cases sometimes to be associated with *E. histolytica* infections. In vagotonia as a rule this is not possible because most cases are due to tubercular glands. Sometimes removal of the nasal disease may eliminate the source of irritation, or diminish the predisposition to nasal catarrh and its subsequent spread to the bronchi. In others the treatment of the enlarged tubercular glands by rest, diet, a healthy climate, and injections of very small doses of tuberculin with secondary vaccines has given great relief.

(C₂) *Increasing the internal defence mechanism.*—In sympathetic predominance we have often found that it is due to deficiency in the thyroid and adrenal secretions. Oliver considers that orchitic substance is also necessary because it oxidises the protein bases into less toxic substances. We first inject m. ii. of adrenalin hydrochloride intramuscularly twice a day for a few days, and then follow it up with the following endocrine extracts by the mouth:—

Extract orchitis vel. ovarii	grs. ii.
Ext. suprarenalin	gr. i.
Ext. thyroideum siccum	gr. ½

Sometimes iodides are useful, and act by supplying the necessary iodine to the thyroid as well as by increasing the expectoration. In the food group, soamin has been shown by Dr. B. N. Ghosh to be useful. We know that arsenic stimulates all assimilative processes, and its excretion in the small and large intestine probably increases the amount of erepsin and so helps to break down the more complex toxic bases into simpler non-toxic bases. When several essential foods produce marked dermal reactions, these are the only possible methods to use, as one cannot eliminate three or four essential foods like milk, flour, eggs and fish from the diet.

In vagotonia there is usually a high blood sugar content, with or without a high amount of adrenalin in the circulating blood. The pulse is often slow with a high blood pressure. Oliver found the anterior lobe of the pituitary gland to be more useful in cases with high blood pressure with a slow pulse. Injections of vaccines raises the immunity the individual against the various infective organisms of the lung or nasal mucosa, but as these persons are sensitive great care should be taken about the proper regulation of the dose of the vaccine. The majority of cases do better if the dose of vaccine is kept very small, for it is rarely necessary to exceed 0.5 c.c. or 50 to 500 million organisms for toxic and non-toxic strains, or 0.000,000,01 milligrammes per c.c. of T.B.E. in cases associated with enlarged tubercular glands.

THE MIGRATION OF HOOKWORM LARVÆ IN SOIL.

By ASA C. CHANDLER, Ph.D.

(Contribution from the Hookworm Research Laboratory, Calcutta School of Tropical Medicine—Jute Mills' Association Endowment).

IN spite of the great amount of interest which has been aroused in hookworm disease in the past thirty or forty years, it is a rather remarkable circumstance that very little really accurate knowledge concerning the free-living life of hookworm larvæ in the soil was available up to three years ago, notwithstanding the vital importance of such knowledge in connection with the scientific control of one of the greatest of human scourges.

Up to 1922 it was the prevalent opinion that after hookworm larvæ had developed to the infective stage and had established their life in soil, they were essentially migratory, and could live for very long periods of time. Dock and Bass (1913), for instance, in their book on hookworm disease, say: "if the temperature is not too low they have a strong tendency to migrate, and especially to crawl up on all sorts of objects kept moist by water."

Nicoll (1917) states that hookworm larvæ can travel through moist soil at a rate of probably not less than five feet per hour, so that, in the course of 24 hours, they may have wandered 40 yards. In my own book on "Animal Parasites and Human Disease" (Chandler, 1922) this statement is quoted and the following comment made:—"While such continuous travelling in a straight line would probably never occur, it is evident that a single infective stool would easily be able to infect the ground for several square yards."

As regards their life span in soil the prevalent conception, until recently, can be illustrated by a quotation from Nicoll (1917). He says "these larvæ when they reach this final stage have ceased to feed, and they can remain alive for months or even years under suitable conditions, i.e., where there is a sufficiency of moisture and not too great heat. In the laboratory they have been kept alive for over 18 months in plain water, at a temperature of about 60°F. It can hardly be doubted that they will live fully as long under natural conditions, unless it be that they are attacked and devoured by other animals, such as aquatic insects."

With the discovery of an efficient method for extracting hookworm larvæ from soil by Baermann (1917) and its improvement by Cort et al. (1922) it became possible to study more accurately the activities, distribution and life of hookworms in the free-living state. In 1922 and 1923 the results of a number of experiments carried out in Trinidad and Porto Rico were published which indicated that our former ideas on these points were quite erroneous. These experiments, in brief, showed that lateral migration does not occur on moist soil, even to the extent of migration to favourable situations when the original environments become unfavourable, but that larvæ are readily carried out from centres of soil infestation by surface water and become established in new places, and that they are readily transferred from place to place by mechanical means, e.g., by soil adhering to boots, etc. (Augustine, 1922a). The absence of any appreciable lateral migration was also observed by Cort and Payne (1922) on a sugar estate and on a cacao estate in Trinidad. It was further shown that, under favourable conditions of moisture and temperature, the larvæ remain on the surface of the soil or very close to it, climbing up on wood, dead vegetable matter, etc., only as far as the film of moisture extended, but not climbing up into the drops of water collected in the axils of leaves of living plants (Augustine, 1922b). Hirst (1924) observed that larvæ placed in an incubator at 37° C. receded into interstices of soil, reappearing and extending themselves from the surface a few minutes after exposure to room temperature. The writer has also

observed this phenomenon when larvæ on the surface of soil were warmed by a Silverman opaque object illuminator attached to a microscope to watch their movements.

As regards vertical migration of buried larvæ, on the other hand, it was found that larvæ under field conditions would migrate in large numbers through at least 36 inches of sandy loam soil, whereas the migration is to a large extent inhibited by fine or clayey soil. In pure clay, migration from a depth of only six inches was unsuccessful. On a wall of soil, however, such as the side of a pit latrine, few larvæ were found above the level of inoculation (Payne, 1923a). Experiments and observations also indicated that migration does not begin until the larvæ have reached the infective stage, that it is stimulated by increase of temperature, that young larvæ show greater activity than old ones, and that the direction of movement is oriented, in part at least, by the movement of the water film over the particles of soil (Payne, 1923b). Rising ground water would, therefore, lead to an upward migration.

As regards length of life of hookworm larvæ in soil under natural conditions, Augustine (1922c) found that a rapid reduction in numbers occurs, and that the extent of their life, under tropical conditions, is limited to about 6 or 8 weeks. Baermann (1917), however, kept larvæ alive in soil for 6 months in Sumatra, and Hirst (1924b) kept them in soil for 4 months in a laboratory in Ceylon during the cool season. The earlier suggestions of Leuckart (1868) and Looss (1911) that the duration of life is directly dependent on the conservation or exhaustion of the stored food granules in the intestinal wall, since the infective larvæ do not feed, were supported by Augustine, who found that environmental conditions such as tropical temperatures, which tend to increase the activity of the mature hookworm larvæ, will shorten their lives by the more rapid using up of the stored food material. The energy necessary for migration has definitely been shown to cause a rapid exhaustion of this reserve food supply, with a consequent shortening of life.

So revolutionary are the conclusions drawn from this work as regards the activity and viability of hookworm larvæ in soil that many workers have hesitated to accept them. It has been suggested to the writer by several eminent parasitologists that there may have been errors in this work, and that the apparent failure of migration and rapid mortality of the larvæ in soil was due in reality to a speedy scattering and consequent "dilution" of the larvæ to such an extent as to make their destruction rather than their migration appear as the explanation.

It seemed worth while, therefore, to test the conclusions reached in Trinidad and Porto

Rico by experiments which would preclude the possibility of the escape of the larvæ by migration. To do this we constructed some large funnels one and a half to two feet in diameter at the top, fitted with burettes underneath. These funnels were filled with water, and circular wooden trays, cut out to a depth of $\frac{3}{4}$ inch and having a narrow rim, were floated on the surface. The trays were lined with absorbent cheese cloth, hanging over the edges into the water at intervals, in order to absorb moisture. Soil was placed on the trays to a depth of one inch, and it was found that any desired degree of moisture could be maintained by regulating the number and size of the overhanging strips of cloth. Five thousand to 10,000 hookworm larvæ were placed on areas of $\frac{3}{4}$ inch diameter at the centres of the discs. In case the larvæ migrated to the edges of the discs they would fall into the water and could be collected from the burettes at the bottom. Water was drawn off and examined at intervals of two or three days, but no hookworm larvæ were ever found, although numerous soil nematodes were collected. At the end of from one to two weeks the soil on the discs was cut into concentric rings and examined from the periphery toward the centre. Four such experiments were carried out, two with each disc. In three of these experiments no larvæ were recovered at a distance of more than $1\frac{1}{2}$ inches from the area of inoculation, and from 75 per cent. to 95 per cent. of those recovered were found in the actual area of inoculation. In one experiment, however, larvæ were found all the way to the periphery of the disc, but in this case the soil was not kept moist automatically, but by daily sprinkling of water on the surface. Although this sprinkling was done with special care to avoid the washing of larvæ from place to place, it is evident that even gentle sprinkling was sufficient to spread the larvæ to a very considerable extent, and that a very slight trickling of water over the surface of soil is sufficient to scatter them.

Another experiment was performed to simulate conditions on a hill-side. One of the discs was sloped at an angle of about 20 degrees, and another at an angle of about 30 degrees, both being kept moist by allowing a very slow stream of water to seep through the soil from the upper side of the disc. At the end of ten days these discs were likewise cut into concentric rings and examined, the upper, lower, left and right quadrants of the rings being separately examined. The soil in these experiments was kept in a saturated condition by the slow flow of the water across it. On the disc sloped at about 20 degrees a total of 15.2 per cent. of the larvæ were recovered; 78.4 per cent. of these came from the area of inoculation, 9 per cent. from the upper quadrant of a ring two inches wide

around the area of inoculation, 6.6 per cent. from the lower quadrant of this ring, and 2.5 per cent. and 3.5 per cent., respectively, from the right and left quadrants; no larvæ were obtained from any of the more distant rings. On the other disc, sloped at 30 degrees, a total of 42.8 per cent. of the larvæ were recovered, 96.93 per cent. of these from the original site of inoculation plus an area of $\frac{1}{4}$ of an inch around it; 1.84 per cent. from the lower quadrant of the next zone of $1\frac{1}{4}$ inches in width; 0.36 per cent. from the upper quadrant of the ring; 0.19 and 0.64 per cent. from the right and left sides respectively, and 0.04 per cent. (2 larvæ) from the lower quadrant of a zone $1\frac{1}{4}$ to $2\frac{1}{2}$ inches from the area of inoculation. It is evident, therefore, that seepage of water down over a sloping hill-side is not instrumental in inducing hookworm larvæ to migrate either upwards or downwards.

As regards vertical migration, feces containing numerous hookworm larvæ were buried under 12 to 24 inches of soil in cylinders having a diameter of $2\frac{1}{2}$ inches. Some of the tubes were moistened from below by standing in water, others were moistened from above by pouring water on the surface. The effect of wetting the soil to a depth of about two inches with weak chemical solutions, such as chloride of lime, copper sulphate, phenyl, etc., was also tested. So few larvæ ever reached the surface in any of the tubes, however, that the differential results were not conclusive. Evidently there was some factor present in this experiment different from those in the field experiments in Porto Rico. Further experiments along this line have been planned.

The vertical migration of larvæ was also studied in glass tubes by direct observation. The tubes were partially filled with dry soil, the larvæ then placed in the tubes with a minimum of water and dry soil placed on top of them to depths of from four to six inches. In tubes in which water was absorbed from below and which consequently had an upward movement of the water films over the particles, the upward migration was very rapid, a few of the larvæ keeping abreast of the rising moisture, but most of them remaining a little distance behind it. The larvæ after half an hour were well scattered from the point of inoculation to the top of the column of soil; none were seen below the point of inoculation. None of the larvæ were observed to climb steadily upward. They moved forward, sometimes as much as $\frac{1}{4}$ inch in a minute, then stopped, and moved sideways and even backwards at times, but the general tendency was invariably upward.

In tubes in which the water was allowed to seep down from above, the movements of the larvæ were very confused. The majority continued to swarm near the level of inocula-

tion for a long time, some moving upward and others downward for distances of about an inch in the course of an hour. It was obvious, however, that the downward seepage of the water had no such effect in directing the migration as had the upward seepage. These tubes were left overnight without more water being added, and in the morning all the larvæ which could be seen were at the top of the column of soil. It is reasonable to conclude from these experiments that larvæ buried in soil are not guided upward merely by an upward flow of ground water as the result of surface evaporation, as was suggested by Payne (1923b), but that they have a definite negative geotropism. An upward flow of water affords very appreciable aid to them, whereas a downward flow retards their progress to such an extent as to neutralise it and prevent migration. The effect can be compared to the help or hindrance afforded to a swimmer by a river current, according to whether he is swimming with or against it. The failure of the larvæ on a sloping disc to migrate with the water seepage is further evidence that the water flow has little or nothing to do with migration.

As regards the migration of larvæ on the side of an earth wall, e.g. that of a privy, which is a matter of great importance, our experiments confirm those of Payne (1923a). We lined the bottom and sides of a petrol tin with soil to which enough clay was added to make it firm. Small holes were bored through the soil from top to bottom in the corners of the tin, and filled with absorbent cotton. By saturating these tubes of cotton with water it was possible to keep the entire soil wall of the tin moist. Feces containing abundant hookworm eggs were placed in the bottom of the tin, at a depth of from ten to twelve inches from the top. Two weeks and three weeks later the surface of the soil around the top of this imitation latrine was carefully scraped off and examined for larvæ. Out of about 1,000,000 possible larvæ, only seven were obtained from these surface scrapings. Charcoal cultures made from the same stools yielded an abundance of larvæ, and large numbers were obtained from the level of inoculation in the tin. In another experiment some pits $2\frac{1}{2}$ inches in diameter and 10 inches deep were made in soil in a petrol tin, and feces estimated to contain over 200,000 eggs placed in the bottom of each. At the end of two weeks the soil on the sides of the pits was scraped off at different levels into a little receptacle, the diameter of which was equal to that of the pit; and which could, therefore, be lowered by a wire into the pit and the surface of the wall above it scraped off so as to fall into it. From $7\frac{1}{2}$ inches to 10 inches above the level of inoculation no larvæ were recovered in any of the pits; from 5 to $7\frac{1}{2}$ inches above,

only 3 larvæ in each of two pits were obtained; from 2½ to 5 inches above, from 3 to 26 larvæ were obtained in different pits, a total of 54 in all four; whereas in the lower 2½ inches and bottoms nearly 10,000 were obtained. The reason for the unusually high mortality in this experiment is not known, since abundant larvæ developed in cultures from these fæces.

To further test this point, soil was scraped from the surface margin of several simple pit latrines which were in constant use in coolie lines on a tea estate in the Darjeeling District where hookworm is known to be prevalent. Not a single larva could be recovered from these scrapings, although the surface of the pit was only about 2½ feet from the surface of the fæcal material contained in it.

It is evident from these experiments that migration on a soil wall such as the sides of a simple pit latrine must be practically nil. Payne (1923b) thinks this is due to an alteration in the flow of ground water, the latter flowing towards the walls of the latrine as well as upwards, as evaporation takes place. In the light of our observations on the effect of the flowing of ground water, however, this explanation does not appear satisfactory. We can, however, offer another possible explanation which seems more probable. We may presume that such larvæ as are not destroyed by lack of oxygen in the centre of the fæcal mass do begin to climb upward toward the surface of the latrine, but that before they have proceeded many inches they climb to the top of some projecting soil particle and remain there, awaiting an opportunity to enter a host, unaware that the entire journey to the top has not been completed. If this is true, it is a fact which is of very considerable practical importance. Further experiments both in the laboratory and in the field are planned to throw further light on this question.

SUMMARY.

The above experiments confirm the conclusions reached by Augustine, Cort and Payne concerning (1) the practical non-existence of lateral migration of hookworm larvæ; (2) the easy scattering of larvæ by surface water; (3) the tendency to upward migration through coarse soil; and (4) the very restricted migration on the sides of a soil wall. Our observations, however, point to a definite negative geotropism as the principal factor in guiding larvæ upward, rather than an upward flow of surface water, as suggested by Payne.

THE CURE OF SCHISTOSOMIASIS BY THE INTRAVENOUS INJECTION OF ANTIMONY TARTRATE.

By Dr. J. B. CHRISTOPHERSON, C.B.E., M.A., M.D.
(Cantab.), F.R.C.P., F.R.C.S. (Eng.),

Assistant Physician to the City of London Hospital,
Victoria Park; late Sudan Medical Department,
Khartoum.

UNDER the title "Experimental Studies in Bilharzia Therapy (*S. spindalis*)," Dr. Hamilton Fairley, in the August 1924 issue of the *Indian Medical Gazette*, published details of a comparative investigation of the action of antimony tartrate and emetine on goats experimentally infected with *S. spindalis*. Dr. Fairley found emetine superior to antimony tartrate as a specific cure for the goats and wrote:—"It will be very surprising if the superiority of emetine hydrochloride does not hold for the human types of schistosomiasis as well."

The method of action of Tartar Emetic in Bilharzia.—In the preliminary sketch giving some details of the antimony tartrate treatment of bilharziasis, Dr. Fairley re-states his original view that antimony does not kill the Bilharzia ova deposited in the tissues, and is of opinion that the

cessation of ova in the urine during treatment is best explained by the temporary sterilization of the worms, the drug acting on the "generative organs of the adult schistosomes." This view it appears has little basis in fact to corroborate it. Dr. Fairley also considers that temporary sterilization of adult worms accounts for the number of cases in which, after treatment, ova have reappeared (in other words "relapses").

References not up-to-date.—The dates of the references which Dr. Fairley gives indicate that he may not have seen all the writings published in 1922, but one in 1923, and none in 1924: for instance, of H. B. Day (1924), of the several Egyptian doctors who have made official reports on the antimony treatment in the six Egyptian Government Hospitals where Bilharzia annexes have been established to carry out the treatment, of F. O. Lasbrey and R. B. Coleman (1924), of F. C. Cawston (1923 and 1924), and most recently of E. C. Faust at Peking (1924).

These are chiefly clinical studies, but their independent work and general agreement are, I think, more reliable than conclusions which cannot so safely be drawn from work done experimentally with a substitute host, and with a parasite of different species to human schistosomes.

Well known workers have advanced the opinion, on logical grounds, that the cessation of ova in the urine during the treatment of bilharziasis by antimony tartrate is due to the direct action of the drug on the ova (miracidia) deposited in the tissues. In the anterior end of the miracidium are head-glands which, according to this view, secrete digestive fluid which penetrates the blunt permeable end of the ovum, and dissolves the tissue ahead, making the progress of the ovum towards the lumen of bladder or rectum possible, not an inherently improbable view, for cercariae are held to have the same mechanism for their passage from the skin into the blood vessel of the host.

H. B. Day, late Professor of Clinical Medicine at Kasr-el-Aini Hospital, Cairo, maintains that not only are Bilharzia ova in the tissues killed by antimony tartrate, but that only a very small dose of antimony is required to kill the ova already deposited ($2\frac{1}{2}$ grains), that the reappearance of ova in the urine after small doses is due to the fact that enough antimony tartrate has been given to kill the ova but not the adult worms, which have only been temporarily inconvenienced by the lesser dose and require a stronger concentration of antimony in the blood to kill them than the ova require. Injections of antimony tartrate are certainly followed by the appearance of dead ova in the urine, and later by the disappearance of the ova from the urine. Where are they killed? Not in the urine, for undiluted urine does not penetrate the ovum. Not in the parent worm, for this would postulate the female schistosome laying addled eggs. They can only be killed in the tissues where they have been deposited.

If such a secretive apparatus as that described above were paralysed, the ovum would remain where it was, for its automotor mechanism would be destroyed, that is few ova would appear in the urine. This view, which has much to support it, was first enunciated by R. T. Leiper in 1919.

Explanation of relapses.—With regard to so-called "relapses" after antimony tartrate in human Bilharzia disease, they are due in uncomplicated cases, practically all of them,* it may be, to want of skill or it may be lack of judgment with regard to dosage on the part of the person who administers the drug. If you give enough antimony you do not have relapses, if you don't give enough you have relapses ("failures"). 25 to 30 grains appears to be the human adult dose (total), and there are very few uncomplicated cases of bilharziasis which require more to completely cure them.

F. O. Lasbrey with an experience of 4,600 injected Bilharzia patients says:—"Failures are always due to the patient not having had the full course." The Egyptian doctors working in the Bilharzia annexes of the Government Hospitals estimate the percentage of successes, in cases treated with antimony tartrate and taking the full course, at over 90 per cent.

Now I think experimental work is liable to failure for the same reason as clinical. Dr. Fairley infected with Bilharzia (*S. spindalis*) 19 goats.

"In 11 out of 19, tartar emetic definitely 'failed to cure'; in 5 complete cure was established." To some he gave 13 injections and to others as many as 45, the total amount of antimony tartrate given varied between $7\frac{1}{2}$ grains and $25\frac{1}{2}$ grains.

Dr. Fairley does not state that he worked out the toxic dose for goats, and in point of fact he appears to have used a very small maximum dose ($4\frac{1}{7}$ grain).

Now it is important that the antimony tartrate should be in such concentration in the blood as to kill the worms. We are completely in the dark regarding the following points:—

(i) The toxic dose for goats. I suspect that a goat would stand more than $\frac{1}{4}$ grain.

(ii) How many injections did each of the 11 failures receive? Injections varied between 13 or 45 it appears.

(iii) Did the 11 failures receive a total of $7\frac{1}{2}$ grains or $25\frac{1}{2}$ grains, or some number between $7\frac{1}{2}$ and $25\frac{1}{2}$ grains?

It is impossible to accept Dr. Fairley's conclusions even with regard to *S. spindalis*, without knowing these details of administration. Whether he is justified in drawing a general conclusion regarding human Bilharzia from the labora-

* It is admitted that certain persons having an idiosyncrasy cannot take antimony tartrate. There are also cases too feeble to take it and certain cases where veins are not easily found. The total of all cases which cannot take antimony is small.

tory experiments with *S. spindalis* is dealt with later.

A personal opinion.—With an experience of over five years with the treatment in England, I state with confidence that my only "failures" have been due to idiosyncrasy of individual cases not permitting the full course to be given; failures have been few (1 or 2). (In England the serious complicated cases of Egypt were not met with, but serious complications only interfere with cure by antimony in so far as they prevent full courses of antimony from being given.)

Apparently cured cases really "failures."—Cases of apparent cures, Dr. Fairley suggests, are "frank clinical bilharziasis" converted into "passive carriers." There appears to be no evidence for the truth of this statement. Mr. N. H. Johnson and the writer during the last four years have had over 150 (injected) cases under observation at the Ministry of Pensions in London and have periodically searched the urine after treatment for ova in each case. In none of those who took a complete course of injections (25 to 30 grains) have living ova returned.

Methods of diagnosis of active Bilharzia.—An experienced laboratory assistant, accustomed to examine Bilharzia urine (and Bilharzia faeces), is able to give a reliable report as regards active Bilharzia infection. The complement fixation test is not infallible, and a cured Bilharzia case will give a positive reaction for a considerable time after completion of the course (and the cure). The complement-fixation test is not yet a practical proposition in the treatment of bilharziasis.

Details which are required from writers reporting "relapses."—Writers publishing "relapses" after antimony injections should always give details of methods adopted, particularly details of dosage, including intervals between single doses, for it is only with such knowledge that a reader can judge whether the recurrence is due to failure of the antimony or to the inexperience of the doctor.

Writers frequently record "failure" after 1½ or 2 or 10, or 15 grains. It would be equally logical to condemn castor oil as a "failure" because a teaspoonful failed to give the required result.

Dr. E. C. Faust's experiments.—Faust recently (1923) made some noteworthy experiments in Peking. He showed that Bilharzia worms in vitro were killed instantaneously in a solution of 1 in 600 antimony tartrate; whilst dilutions of 1 in 42,000 killed in 60 mins.

If these findings are confirmed, the direct action of antimony tartrate in the case of Bilharzia adult worms must be admitted. Incidentally Faust observed also that the worms appeared to die from the posterior end forwards.

Dr. Fairley's theory of the action of antimony tartrate picking out the generative organs of Bilharzia does not appear to be supported by Faust's experiments.

Dr. Fairley's experiments.—With regard to the experiments with antimony tartrate on *S. spindalis* in goats, if it is true that antimony tartrate is less toxic than emetine to *S. spindalis*, in Fairley's cases antimony proved less toxic than emetine to the goats, for the emetine killed three goats. This corresponds to experience in human schistosomiasis. Emetine with its liability to complications, cardiac depression and peripheral neuritis, is more toxic to the "host" than antimony tartrate.

Clinical investigations recorded support antimony tartrate versus emetine for Bilharzia.—Investigations were as a fact carried out (1923) at the Kasr-el-Aini Hospital to determine the relative value of antimony tartrate and emetine in human Bilharzia disease, and the conclusion arrived at was that emetine was *not* as efficient as antimony tartrate in human bilharziasis. Emetine has also the disadvantage of being considerably more expensive than antimony tartrate, and it must be remembered that there are millions of Bilharzia sufferers waiting for treatment in Africa and 10,000,000 in China; the price of emetine makes it prohibitive for mass treatment.

It is not easy to carry on clinical investigations with human schistosomes and with the human host in India. Even if it be proved that emetine is more toxic to *S. spindalis* than antimony tartrate, it has not been shown that man ever is a host for *S. spindalis*.

The selective action of antimony tartrate.—Intravenous antimony tartrate in schistosomiasis has two distinct bio-chemical actions, parasitocidal and physiological; or using Ehrlich's terminology, parasito-tropic attraction for the parasite and organo-tropic affinity for the tissue cells of the host. Antimony is curiously selective both as regards the parasites and the organs and tissues it affects.

Aragao and Vianna.—It would seem that it has a parasito-tropic action on some bacteria and not on others—the organism of ulcerating granuloma of the pudenda,* for example.

Antimony tartrate has a parasito-tropic action on the Leishman-Donovan body, but no appreciable effect on other protozoa.

Antimony tartrate has a parasito-tropic action on all forms of human schistosomiasis, but it has no known action on other helminthic worms or even on other trematodes (e.g., *Fasciola hepatica* the liver fluke of sheep, man, etc.). And this parasito-tropic action appears to vary in intensity in individual worms or broods of the same species, selecting or picking out one brood more readily than another; this is possibly the reason why some adult cases of Bilharzia may be cured by as little as 15 grains of antimony tartrate, whilst others take 30 grains.

With regard to organotropy, antimony appears to select certain tissues and organs, but not always

* *Bacillus mucosus capsulatus*—one of the suspected causes of the disease.

the same organs and the organs not always to the same extent. The liver, kidneys, the brouchial passages, cutaneous tissues, muscles, etc., appear to be selected, but somewhat capriciously, hence the variety of symptoms produced when antimony tartrate is injected intravenously.

Therefore it would not be surprising if the intensity of action of antimony tartrate varied according to the species of schistosome, and that it was less toxic to *S. spindalis* than to human schistosomiasis.

The sphere of purely laboratory work.—It would appear that sometimes laboratory work is given a position of more importance than clinical work. Laboratory work with regard to the action of drugs is certainly useful for preliminary investigations regarding dosage and to investigate details which necessitate the death of the host and to elucidate points which can be investigated with laboratory apparatus alone. But where investigation can be made by using exactly the paraphernalia from which the conclusions are to be drawn, clinical observations are needed, and laboratory work is not acceptable as a substitute.

Lower animals, test tubes and substitute conditions cannot take the place of investigations carried out under natural conditions.

The problem antimony versus emetine is an important one for India, where schistosomiasis probably exists in localities where it has not yet been identified.

F. Milton has privately reported cases from Ooty which he suspects to be intestinal schistosomiasis, and J. P. Cullen (Namtü) has already reported the Yunnan Province of China to be an endemic area, and the adjacent portion of Burma and the Schwelin tributary of the Irrawaddy to be infected.

THE TREATMENT OF STIFF JOINTS.

By H. HALLILAY, M.B.,

LIEUT.-COLONEL, I.M.S.,

Lahore.

PROBABLY no profession in the world is more under the tyranny of the "hypnotic phrase" than is the medical profession. By the expression hypnotic phrase I mean a phrase which puts the judgment to sleep and paralyses all movement towards investigation in the mind.

Unfortunately in our profession the science of words forms no part of the training of a medical man: it is an essential part of the education of a lawyer.

The particular phrase to which I wish to draw attention in this article is "the breaking down of adhesions," a fine old hypnotic phrase which has done a vast amount of harm in its day, and will, I have no doubt, survive to do more harm yet in the future.

The application of the phrase is as follows:—

A man, woman, or child breaks an arm or sustains an injury in or in the neighbourhood of a joint. After a longer or shorter period of immobilisation according to the therapeutic leanings of the particular surgeon or physician who has been called in to the sufferer, a degree of stiffness sets in in the neighbourhood of the joint. The time is now ripe for the medical attendant to do what he calls breaking down the adhesions. This is usually done under an anæsthetic, as in the first place the sentinel muscles would resist up to the point of their own rupture the trauma and violence to which it is proposed to subject the shortened ligaments and fasciæ about the joint, and secondly the pain entailed would be far too great for any one to endure without an anæsthetic.

The limb is forcibly straightened under the anæsthetic with the result that the next day the patient is unable to move the limb at all owing to the acute pain, swelling, and inflammation following the trauma to which the limb has been subjected.

After two or three repetitions of this treatment the range of movement usually becomes progressively less, and the sufferer seeks some less strenuous form of therapeutics. He is liable to end by placing himself in the hands of one of the great army of irregular healers and his case will probably go to

glorify the literature of the era, the Christian scientists, the electro-manipulators, the osteopaths or the homeopaths. Thus is one more sheep lost from the flock of the true believers, owing to a too rigid application of dogma.

At the best the patient is left to the ministrations of a competent masseuse or masseur, who by their patient stretchings will in time undo the damage done by the violence to which the structures have been subjected and will, in time, lengthen the shortened tendons and ligaments so that the joint will be able to regain a measure of its former usefulness.

I do not wish it to be thought that I am condemning the treatment of all stiffened joints under an anæsthetic; far from it, it is a most useful treatment in the proper class of case, but it is as well to make sure that the case is one to which this treatment is appropriate.

In what class of case is this treatment suitable? The class of case in which this treatment is suitable is that in which there are either within or outside the joint adhesions which definitely limit the movements of the limb. It is difficult to define by words the exact sensation of the limitation imposed by adhesions to the manipulations of the surgeon, but it is a very definite one and unmistakable to an experienced hand. It is quite a different feel to the unyielding jar of a bony obstruction which is usually painless; it differs again from the elastic resistance of shortened tendons and muscles, which is, by the way, often extremely painful.

There is usually some degree of free movement, nearly always limited in the direction of extension, but very definitely checked as soon as the limiting band is fully extended. Any attempt to pass that limit is accompanied by pain. This is the class of case which was the foundation of the bone-setter's fame and income. These stiffened joints formed the arenas in which the bone-setter gained many a victory over the legitimate professors of the healing art, who too often alas! had to retire from the contest with humbled crest and damaged reputations.

The history of a typical case is as under:—

A sporting peer has injured his knee when hunting. After some months' treatment by his regular medical attendant he becomes disgusted and is advised to go to Mr. Blank, the bone-setter, who has so many successes to his credit in this class of case. He limps into the consulting room on crutches and ten minutes later marches out briskly and returns to his residence on foot, his now useless crutches following him in the conveyance which carried him to the house of the bone-setter.

This apparent miracle was brought about as follows:—The bone-setter, by a series of rotary movements designed to throw the sentinel muscles of the knee off their guard, with a sudden brusque movement fully flexes the joint.

A tiny report is often audible as the adhesion snaps, due, the bone-setter assures the patient, to the "going

in" of the displaced bone which has been the source of all the trouble.

The moral effect on the patient is great, both from the obvious freedom of the joint after months of disability and from the confident injunction to walk without fear of ill consequences. As the anatomical knowledge of the patient is unlikely to be greater than that of the bone-setter, his pathology is accepted by the former with proper submission.

After a due measure of denunciation of the quackery of the bone-setter, the "legitimate profession" quietly adopted the manœuvres on which his practice was founded, without, I fear, any very public expression of gratitude for the gift which had been made to them.

Here was a real advance in the treatment of injuries to limbs, but, admirable as it is in properly selected cases, it is not of universal applicability.

Simple fractures in and about the neighbourhood of joints are very unlikely to produce adhesions in the proper sense of the term. What is produced after prolonged immobilization is "contracture" of muscles, and in time shortening of ligaments and fascia.

All that has happened is that the muscles, in obedience to that law which bids them shorten if their points of origin and insertion are approximated for any length of time, have taken up the slack and adapted their length to the new conditions. Half the devices of orthopædic surgery depend upon this property of voluntary muscle, such as the crooked heel and the thickening of the inner side of the boot-sole in the treatment of flat foot.

It should be obvious that violent wrenching and traumatisation of such shortened muscles and structures can only result in an increase of the original disability.

The following case will illustrate my meaning:—

Mrs. A. in 1917 fractured her right arm; the fracture was "plated," the plate was subsequently removed and for some reason the arm was immobilised for a prolonged period.

When told that she might now use the arm without fear of re-fracturing it, it was found that there was very considerable difficulty in separating the elbow from the side, all the muscles opposing this movement having shortened owing to the prolonged immobilization to which the arm had been subjected.

As the surgeon who had originally operated on her arm had returned to England, she consulted another practitioner who told her that the cause of her disability was the formation of adhesions in and about the shoulder-joint and that all that was necessary to restore the joint to its former usefulness was to "break down" the adhesions which had formed. This was accordingly done under an anæsthetic, with the result that she was unable to move the limb at all for some weeks. As she did not improve, the procedure was repeated after a few months but without benefit.

The patient came to me in May, 1921.

The shoulder was fixed and she could only abduct the elbow 4 inches from the side; all other movements of flexion and extension were similarly limited. She was placed in charge of an experienced and competent masseuse, who was instructed to use no violence and to give

the patient as little pain as possible as the treatment would of necessity be a prolonged one.

At the expiry of four months she had almost completely regained full movement, a very happy result, to which the pluck and perseverance of the patient very materially contributed. I regard the assistance and co-operation of a trained masseuse as essential in this class of case, as without their moral support the keenest patient loses interest in carrying out exercises which yield such a meagre harvest of results daily.

A very great and important part of the treatment consists in the performance of voluntary movements by the patient, which explains the slowness of progress in the case of children who do not see the importance of their co-operation in the treatment.

Many of these cases need never have arisen had movements and judicious massage been instituted within a few days of the occurrence of the injuries; the very surest way to produce them is by prolonged immobilization.

It may be thought that I have discussed this subject at undue length, but the importance of a disease or disability is to be measured rather by the number of those who suffer from it, than by its rarity: these conditions are so common and the results are so frequently unsatisfactory both to patient and to medical attendant as to excuse my prolixity in a consideration of their treatment.

DETAINING OF PATIENTS.

By C. C. MURISON, F.R.C.S.E., D.P.H., D.T.M., etc.,

LIEUT.-COLONEL, I.M.S.,

Civil Surgeon, Belgaum.

By "the detaining of patients" is meant the keeping of patients in hospital, from a few hours to three or more days, without entering their particulars in the register of in-patients, or showing them as in-patients in any of the records of the hospital.

The health of institutions, such as prisons, schools, factories, departments, etc., is estimated, not by their sickness, but by statistics such as:—

Annual ratio of admissions per 1,000 of strength.

Annual ratio of constantly sick per 1,000 of strength.

Average annual number constantly sick.

Average sick time to each person.

The above statistics are based either on the total number of in-patients or on the number of days spent in the hospital by each of these in-patients. Consequently, with a view to showing a good health record, many, if not all, of these institutions have adopted the system of "detaining" patients in the hospital for mild ailments, for one, two, three or more days and then, if necessary, of admitting them as in-patients. This means that the particulars of these patients during their detention are not entered in the register of in-patients, with the result that:—

(a) the total number of the in-patients is reduced, as many of the detained cases recover during the period of their detention and leave the hospital without being admitted as in-patients;

(b) the total number of days spent in the hospital by the in-patients is reduced, as the days of detention in the hospital, if any, prior to being admitted as in-patients, are excluded.

There is no uniformity in the different institutions with regard to this system of detaining patients in hospital, as will be seen from the following:—

(1) There is no definite standard of illness to decide when to detain and when to admit.

(2) All severe cases of sickness are admitted into the hospital without any detention.

(3) Some institutions detain patients for 1 day.

(4) Some institutions detain patients for 2 days.

(5) Some institutions detain patients for 3 days.

(6) Some institutions detain patients from 1 to 3 days according to the merits of each case.

(7) Some institutions, on deciding to admit a detained case as an in-patient, do so from the date on which the decision has been made—that is, after the patient has been detained for one or more days. This is wrong, as the days of detention will be excluded from the actual number of days spent by the patient in the hospital.

(8) Some institutions, on deciding to admit a detained case as an in-patient, do so from the date the patient was detained in the hospital under observation. The usual practice of these hospitals is to enter the particulars of this patient after the particulars of the patient last entered in the register, and grant him or her the next consecutive number in the appropriate group. This means that the actual date of the patient's admission is entered, perhaps, many days out of its proper place and the register number is not in its sequence. In large hospitals, with many admissions daily, the patients under this system may have their particulars entered in the register quite one hundred places out of their proper place. Hence this system causes great confusion.

Under these circumstances the returns and the statistics of similar institutions are very badly "cooked" and are incomparable, and so they are, to all intents and purposes, useless.

An argument put forward for detaining patients for one day is that their meals are supplied to them from their unit cook-house, while, if they were admitted as in-patients, they would get their meals from the hospital, and so the rations drawn by the unit cook-house would be wasted, and in the case of large numbers of patients this wastage is well worth consideration. This argument may be feasible for patients detained in the hospital for one day, but it is certainly not so for the

patients detained for two or more days, nor for patients admitted into the hospital as in-patients without detention. Quite a large number of the patients with acute illnesses, whether admitted as in-patients or detained, are not able to take their ordinary meals, and so have to be supplied with milk, either as a diet or as an extra from the hospital, with the result that their rations drawn by the unit cook-house will be wasted as far as the institution is concerned. From the above it will be seen that in institutional hospitals the system of detaining mild cases is not a good one, and so it is recommended that all patients taken into the wards should be admitted as in-patients and not detained, and thus be a true index of the health of the institution, if this is based on the number of the in-patients.

In some institutions there is a rule that an employee is entitled to a certain amount of leave in the year, but the days spent on the sick list are deducted from the amount of leave due. Therefore with the view of doing a mild case a "good turn" he or she is shown as detained, and neither admitted into the hospital as an in-patient nor on the sick list in his or her quarters. The result of this is that the days of detention are not reported to the proper authorities, and consequently are not deducted from the leave due to the individual. This, for reasons quite obvious, is fair neither to the employer nor to the other employees, who have to do the detained individual's work. This system of detaining patients either in or out of the hospital with the object of doing him or her a "good turn" may actually do him or her harm, as seen from the following case:—

Many years ago a patient had many attacks of malaria over a period of about a year and a half, for which he was detained in the hospital for a few days each time, instead of being admitted on the books as an in-patient. This malaria made him depressed and he felt that a change to Europe was essential, and so he claimed leave and a free passage to England, in accordance with the terms of his agreement. He was asked to produce a medical certificate in support of his claim, which the officiating medical officer had great difficulty in granting, as the individual concerned as stated above had not been admitted as an in-patient of the hospital, and so there was nothing to show evidence of the frequent attacks of malaria. Further, the officiating medical officer was placed in the awkward position of having to avoid showing up the system maintained by the permanent incumbent of the appointment.

Some institutional hospitals have the system of detaining in the wards individuals under observation, in preference to admitting them as in-patients. Persons who are malingering attend the hospital, with the object of being detained in the hospital, so as to avoid work, duty, school and such like. These patients are detained in the hospital for observation, and if they are found

to be suffering from a disease and requiring admission as in-patients, their particulars are entered in the register of the in-patients, either from the date on which the decision was made or from the date the patient was detained. The merits and demerits of these dates will be seen respectively in (7) and (8) above.

If they are found to be suffering from no appreciable disease (N.A.D.), they are discharged from the hospital, and not shown in any of the records of the hospital, except, perhaps, by a note made in some scroll book. The reason put forward by some for this procedure is that it shows a better health record of the institution. This is no reason, as the health of the institution cannot be affected by them, as, if admitted, they will be shown as "N.A.D." and not included amongst the statistics of the diseases, on which the health of the institution is based. Consequently it is strongly recommended that these persons under observation should be admitted as in-patients of the hospital, and given serial numbers in the ordinary group in preference to detaining them. In the event of their being found to be suffering from a disease or an injury, they merely continue with the serial number granted to them, and the disease or the injury is entered in the column for the diagnosis. In the event of their being found to be suffering from neither a disease nor an injury, then one of the following two methods can be adopted:—

(a) Let them continue with the serial number in the ordinary group, and at the foot of each page of the register make progressive totals of the ordinary and N.A.D. cases, thus:—

On page 1.....	Ordinary cases = 18.
	N.A.D. cases = 2.
On page 2.....	Ordinary cases = 18+19=37.
	N.A.D. cases = 2+1=3.
On page 3.....	Ordinary cases = 37+17=54.
	N.A.D. cases = 3+5=8.

and so on.

This means that the last serial number of each group of patients does not indicate the total number of the admissions in that group, and so this system is not recommended.

(b) As soon as the case is diagnosed as "N.A.D.", adopt the following procedure:—

(1) Enter "N.A.D." in the column for diagnosis.

(2) Place "N.A.D." before the serial number in the group column of the register. Suppose the serial number is 15. By placing "N.A.D." before it, this converts it into N.A.D. 15. The result of this is that this case cannot be included amongst the total number of the cases admitted under the ordinary group.

(3) In the remarks column of the register, against 15 (or as now converted into N.A.D. 15) state "Rectified by 86A." (The latter number 86A is merely an assumed number used for convenience of explanation.)

(4) In the remarks column of the register against 86A state "To rectify N.A.D. 15."

(5) The next patient after 86A in the ordinary group must be numbered 87.

Mental or police cases suspected of malingering are detained for observation in certain hospitals. These patients, if found later to be suffering from disease or from the effects of drugs, etc., are admitted into the hospital as in-patients either from the date on which the diagnosis was made, or from the date on which the patient was detained, and if they are found to be suffering from no appreciable disease (N.A.D.) they are discharged from the hospital. The reasons put forward for detaining these patients in preference to admitting them is that they cannot be admitted as in-patients till they are found to be suffering from disease and require treatment. This is not a good reason, and so with a view to simplifying the admissions, returns, and the dieting of them, etc., it is recommended that all these patients should be admitted and dealt with in a similar manner to the patients detained for observation in institutional hospitals described in the last few paragraphs.

Institutional hospitals frequently detain in the wards, in preference to admitting them as in-patients, individuals who have been inoculated or vaccinated for prophylactic reasons, on the grounds that they are suffering from a reaction only, and not from any disease, and so they should not be included amongst the sick of the unit. If they were included, the health of the institution would appear to be worse than it really was. It is essential that a record should be kept of these reactions, and the number of days spent in the hospital by each individual, and so it is recommended that these persons should be admitted into the hospital and granted serial numbers with "D" before them. The "D" stands for "Detained," and so this will prevent these cases from being included amongst the figures of the diseases, on which the health of the unit is based. By their admission there is no difficulty of dieting them from the hospital.

It may here be stated that in some institutional hospitals patients suffering from reactions following inoculations or vaccinations for prophylactic reasons are admitted into and shown as in-patients of the hospital and are diagnosed as "effects of, say, anti-typhoid vaccine." There is no such disease as "effects of anti-typhoid vaccine" in the "Nomenclature of Diseases," and so when the statistics are worked out these cases are ignored, but they cause confusion and perhaps additional work. Consequently the author recommends the method given in the last paragraph.

Persons who are "carriers of disease" are frequently taken into hospitals, and the question has arisen as to whether they should be shown as in-patients or detained in the hospital. If admitted,

difficulties arise as regards the statistics of the hospital as they are really not suffering from the disease, and if detained difficulties arise about their diets. Consequently the method mentioned in the paragraph before the last is recommended to be adopted.

The following are the kinds of disease carriers:—typhoid fever, paratyphoid A. fever, paratyphoid B. fever, diphtheria, dysentery, cholera, etc.

In most hospitals there is a practice of detaining out-patients in the wards so as to enable them to get over the effects of operations and anaesthetics. The period of detention varies in most hospitals, and also in the individual cases, but it is usually from about one or two hours to technically two days. This system of detaining out-patients may not be important from a statistical point of view, but it is from a financial point of view, as seen in the following cases:—

In a Venereal Disease Clinic in the United Kingdom the out-patient department is under the control of the Local Municipality, and the attached wards are under the control of the hospital, which depends on charity for its financial support, and both of them are managed by the same staff. The local authority (Municipality) is charged 5 shillings a day for each "venereal" patient admitted into the wards. In this clinic the practice, after lumbar puncture, of which cases are numerous, is to detain, in the wards, out-patients for nearly 24 hours, which period is technically, according to the rules of most hospitals, two days. These patients, while in the wards, are given a bed, towel, light diet such as tea, milk, sugar, bread and butter, and perhaps also have to be nursed. This system raises several points, and their discussion is beyond the scope of this paper, except that all will agree readily that it is quite wrong for a hospital depending on charity for its finances not only to be deprived of ten shillings, but also to be put to the additional expense of supplying diet, linen, etc., for each of these patients for two days.

In many hospitals the number of out-patients detained in this way for several hours a day numbers over a thousand a year, and yet the medical and the nursing staff do not see that this procedure, to put it bluntly, is cutting their own throats. These out-patients, if admitted into and discharged from the hospital on one and the same day, will be technically one day in the hospital, and so they will increase the number of not only the in-patients, but also the daily average of in-door sick of the hospital. The ultimate result of this will be that the budget allotment for the nursing and the other staff, and also for diet, bedding, drugs, etc., can be so increased as to make the great difference of managing the hospital more efficiently. The author has seen the budget of a hospital increased for the above reasons, with the further result that the hospital personnel was increased. In addition, all the paying patients paid the in-door charges according

to the accommodation they received. In another hospital this system of admitting these patients had the effect of converting a second class hospital into a first class, with consequent increase of personnel and equipment, and even in the salary of some of the staff. It has been and will be argued that none of these patients operated on and detained for a few hours should be shown as in-patients. Pending the decision of a central authority, the author is of the opinion that these patients should be shown as in-patients if they:—(a) are taken into the wards, or (b) remain in the out-patient department for more than two hours.

LEFT-HANDEDNESS.*

By PRAKASH CHANDRA DAS, M.B.,

Medical Officer, Ranchi European Mental Hospital.

THE subject of this evening's paper is left-handedness, which is also termed sinistrality or manciniism. At the outset it is important to state what this term really means. Hugh Gordon¹ describes a left-handed person as one who would use the left hand in preference to the right in all actions which are usually done by the right hand in the case of a right-handed person. Moutier (quoted by Hugh Gordon) also states that a left-handed person is one who habitually does with the left hand a series of professional and customary acts generally done by the right hand in the case of the right-handed, and that the ambidextrous are those who do these acts with either hand indifferently.

In the popular mind there is a universal idea of inferiority, awkwardness or unfavourableness associated with left-handedness. For example when we speak of a left-handed compliment, which is worse than damning with faint praise and is disliked by all. Again we call it a left-handed marriage in which the bride-groom gives his left instead of his right hand to the bride as in a morganatic marriage, which is an inferior form of marriage of a male member of a royal family with a woman of inferior rank—hence a left-handed wife, a left-handed son. Again we Indians use the left hand in performing unclean actions, as for example, washing ourselves after answering the calls of nature. Similar examples can be multiplied. On the other hand, the right hand has been given the place of honour,—as when we speak of a company's right-hand man, or even of an error or the like, we say "too great generosity is a right-handed fault." We Indians, whenever we offer anybody

anything, generally do so with the right hand. The act of blessing is universally performed with the right hand. Many other examples might similarly be mentioned.

Now let us turn our attention to some experiments made and conclusions drawn from them by scientific men in this connection. In an investigation by Hugh Gordon in the elementary schools in Middlesex and London, he found the following:—Out of 3,298 pupils examined, he found 241, that is to say 7.3 per cent. left-handed; whilst in the mental defective schools, out of 4,620 students 843, that is to say, 18.2 per cent. were found left-handed. There appear, therefore, to be more than two and a half times as many left-handed children in mentally defective schools as in ordinary schools. Ballard² notices a higher percentage of left-handed children in mental defective schools than in ordinary elementary schools, i.e., 6.5 per cent. against 4.1 per cent.; whilst

* An abridged form of a paper read before the Ranchi Medical Society on 2nd August, 1924.

others, e.g., Franklin Jones, Josefa Ioteyko, etc., put down the percentage in ordinary schools at a still smaller figure than the above. Again out of 374 boys in special schools, Hugh Gordon found 61, i.e., 16.6 per cent. left-handed, while out of 355 girls 76, i.e., 20.7 per cent. were found left-handed, thus showing that left-handedness is more common among girls than among boys. J. Jackson⁸ refers to the opinion that the insane have a great percentage of partial ambidexters in their ranks, and that there is a high percentage of left-handed among criminals. Mayet found a high percentage (16 to 30) of ambidextrous and left-handed among idiots and epileptics. Prof. Lombroso⁴ says "Left-handedness is a sign of degeneracy."

Out of 9,176 boys in 407 lower primary schools in the Jamui subdivision of the Monghyr District there were 8, i.e., 0.09 per cent. left-handed, and of these 8, 3 were stammerers. Again out of 276 patients at the Patna Mental Hospital 12, i.e., 4.3 per cent. were found left-handed (cf. this 4.3 per cent. with the above 0.09 per cent. in elementary schools). Out of 345 pupils in the Hazaribagh Reformatory School, 5, i.e., 1.4 per cent. were found left-handed, (cf. again this percentage with 0.09 per cent. in elementary schools). Out of 205 inmates of the Juvenile Jail at Monghyr only one, i.e., 0.4 per cent. was found left-handed. In the Ranchi European Mental Hospital out of 151 patients of whom 76 are males and 75 females, 10, i.e., 6.6 per cent. were found left-handed. And of these 10, 8, or 10.6 per cent. were females and 2, i.e., 2.6 per cent. males, thus showing a much higher percentage of incidence in females.

All these figures clearly show that the percentage of left-handedness is much higher in an abnormal class of people, e.g., mentally defective, insanes, truants, incorrigibles, criminals, etc. Hence left-handedness can hardly be considered as a normal variation. On the other hand very rare cases can be cited of left-handedness associated with an extraordinary degree of intelligence or capability. Minute inquires in many of these cases may show either that they are forced to be left-handed owing to circumstances, e.g., loss of the right arm, hand, even right thumb, injuries to the nervous or muscular systems, or various degrees of functional disorders of the mind, e.g., psychoneurosis, neurosis, psychosis, etc.

Besides what has been said above, left-handedness has been found to be very commonly associated with mirror writing. Mirror writing is a form of writing in reversed letters which can be easily read with the help of a looking-glass. Hugh Gordon⁶ says "Early in the investigation it was noticed that there was a much higher percentage of mirror writers among children, who, although they

wrote with the right hand, were evidently left-handed in many other of their activities." Ballard⁶ says about mirror writing "With rare exceptions it is done by the left-handed people only, and with the left hand only. The subject does not recognise at first the word as he writes it down. A. L. Beely, Instructor in Psychology, Utah University, after investigation in the schools of Chicago in 1918, says that mirror writing is a characteristic of extreme left-handedness. Ireland⁷ also mentions that mirror writing is common among the left-handed. The specimens of mirror writing shown here were produced by the patients when they were asked simply to write with the left-hand and without any suggestion of any kind, but it was interesting to observe them writing thus without detecting their own mistake and correcting it. L. G. Fildes and C. S. Myers⁸ report an interesting case of extreme left-handedness and reversal of letters. This was a markedly left-handed boy of about 7 years of age. His maternal grandfather, his maternal uncle, and a son of that uncle were also left-handed. The boy knew some, but not all of the letters of the alphabet, and all the ten Arabic numerals. He had just begun to be taught to write with his right hand, but he found the greatest difficulty in doing so, owing to the coarseness and the want of co-ordination of the movements of that hand. For these reasons and especially because he began to stutter, he was soon allowed to write with his left hand only, whereupon the confusion of the positions of letters and the disturbance of speech rapidly disappeared. Another interesting case of a left-handed child has been mentioned by a correspondent, H. A. Clowes.⁹ She is a decidedly left-handed child and all movements requiring skill, such as threading, a needle, drawing, and attempts at writing, are performed with the left hand. When writing the capital letters of the alphabet without a copy, the letters which should turn to the right are turned to the left and vice versa as in B and E, and when drawing a face in profile the face is made to turn to the right, which is quite unusual with right-handed children. Attempts to use the right hand for drawing, etc., are very unsuccessful and are made with painful efforts. She says they make her feel sick. In another case in the *British Medical Journal* of 24th May, 1924, it is said that it caused the child pain and sickness when she was made to write with her right hand, but with her left she wrote easily, though it was backwards. Another very interesting case of mirror writing with some drawings has been described by J. L. M. Symms¹⁰. In this case, on the left-handed child being asked in her scripture class to draw the story of the "Three Wise Men," she cried bitterly because she was unable to depict

them walking towards the manger. There is a boy in the Kanke (Ranchi) Lower Primary School, of about six years of age, who is just learning his alphabet; he writes correctly with facility with the left hand, but writes with the greatest difficulty with his *right hand*, and then only in mirror fashion.

After experiments on the problem of mirror writing, L. G. Fildes¹¹ comes to the following conclusions:—(1) Mirror or reversed writing is very commonly found among young children and defective children. It varies in kind from occasional reversal of single letters to a complete reversal of all words and letters written (true mirror writing). The latter, however, is comparatively rare. (2) It is found most frequently in association with left-handedness, but it also occurs in varying degrees among right-handed children, who have never written except with the right hand. (3) It occurs both in copying letters and in writing from memory. There seems no doubt that the tendency to reverse letters seen in mirror writing is only part of a larger tendency, especially among young children, to reproduce forms without any apparent heed to the position which they occupy in space. In support of the last view expressed above, I may mention with profit some similar observations made by Major Berkeley Hill and Prof. Henry Head, who in course of his correspondence with the former, in reply says: "I am much interested to hear what you say about the way in which some of the native troops (of Uganda) read with the books upside down; this is a well known condition in children. Many children are quite content to look at pictures upside down or sideways, and it makes no apparent difference to them that the figure is the wrong way up. Occasionally this peculiarity persists even after they are able to read."

Squint has also been found in many cases to be associated with left-handedness. Out of 10 cases of left-handedness in the Ranchi European Mental Hospital, 5 have squint also. W. S. Inman¹² says that he investigated 150 consecutive family cases of squint. In 13 the patient was a non-squinter, giving a family history of the three conditions, viz., squint, left-handedness and stammering. Out of the remaining 137, all of whom were squinters, 33 or 24 per cent. were left-handed. Again out of these 137 squinters only 19 were stammerers, while four cases showed all the three conditions, viz., they were left-handed, they stammered and they squinted. In an address on "Squint, Mancinism, and Tubercle," W. C. Rivers¹³ says that out of 120 cases of squint investigated 10 were left-handed and all these 10 were *left-eyed* squinters also. In another place he quotes Lombroso and Fere, according to whom mancism has

been reckoned among the stigmata of degeneracy. He also quotes Markel and others who say that savages, lunatics and criminals show excess of mancism.

To quote Hugh Gordon again, he says that Ballard and others have shown that stammering is more prevalent among left-handed children who write with the right hand, than among pure left- or right-handed children. Out of 10 left-handed patients of the Ranchi European Mental Hospital, there are three only who are defective in speech, (I mean defective in articulation).

In conclusion, it may not be out of place to describe the cases of left-handedness in the local mental hospital:—

1. Miss G.—Imbecile, left-handed, squint in both eyes, left more so.
2. Mrs. C.—Maniac-depressive insanity; left-handed; has high errors of refraction, mirror writer.
3. Mrs. Bk.—Secondary dementia, left-handed, squint in the left eye alone.
4. Miss Bl.—Imbecile, left-handed, squint in both eyes; defective speech.
5. Mrs. A.—Dementia præcox; left-handed.
6. Miss M.—Epileptic, left-handed, squint in the left eye and defective speech.
7. Mrs. T.—Dementia præcox; left-handed.
8. Mrs. H.—Maniac-depressive insanity; left-handed; mirror writer.
9. Mr. B.—Imbecile, left-handed, squint in both eyes; mirror writer.
10. Mr. S.—Imbecile, left-handed, and defective speech.

In a subsequent paper I hope to deal with the causes of left-handedness and mirror writing and some problems connected with them.

MARCH.

LEPROSY RESEARCH.

THE *Annals of Tropical Medicine and Parasitology* of October 31st, 1924, contain the Croonian Lectures on this subject by Sir Leonard Rogers. In the first lecture the association between leprosy incidence and atmospheric humidity is discussed. Among the conditions influencing the prevalence of leprosy are:—

(1) The general hygienic condition of the people.

(2) The introduction of infected persons.

The communicability of the disease is regarded as being established, though the precise manner of transfer of the infection has not been cleared up.

Long and close association with a leper is usually the history of the affected person, but sometimes a single close contact with a leper appears to have been enough to convey the infection.

The active nodular form is much more dangerous than the late nerve type, and children are much more susceptible than adults. Congenital leprosy is extremely rare, and the segregation of infants from the leper parents is essential. The modes of infection may be (1) by the skin, through wounds or abrasions which become contaminated with infective material, either by contact with the leper or by wearing his clothes. (2) The nasal mucosa is not so likely a channel of infection as has been thought. (3) Flies, mosquitoes, bed bugs and other insects are under suspicion.

The best method of prophylaxis is segregation, this has always been effective wherever it is properly carried out. Sir Leonard gives some interesting examples of isolation laws which have been enforced from the time of Moses. In Nigeria all young lepers were killed, in Sumatra they were buried alive, in Western India they were drowned. The most effective segregation of modern days was carried out in Normay, where the disease in 1856 was much more common than it is to-day in India. Now the new cases are only 2.5 per cent. of the number occurring when segregation was started. In tropical countries the difficulties are much greater than in European countries and effective segregation is admittedly impracticable. The policy advocated by Sir Leonard consists of:—

(1) The encouragement of effective early treatment, which is popular wherever it is properly carried out. The result of this is that the persons affected rarely reach a stage of the disease at which they become highly infective; while

advanced cases also become less dangerous to the community.

(2) Careful observation of the persons who have come in contact with other cases, so as to detect the disease at the earliest possible moment.

(3) The isolation of the advanced infective cases in special hospitals and colonies.

Experience in Honolulu is said to show that it is possible to diminish the number of lepers in a community by one half in ten years. When the numbers have been brought down to a considerable extent, it will be possible to increase the efficiency of treatment and control, so that progressively more rapid elimination of the disease can be expected. The detailed programme varies according to the conditions of each country; compulsory segregation is suitable only in countries where public opinion is sufficiently advanced, but in India the work will have to be carried out on a voluntary basis. Large colonies are advocated with ample land available for cultivation, so that highly infective patients can be kept under conditions which are favourable to their recovery, while the community is protected against contact with them. The early and less infective cases can be dealt with at hospital and dispensary clinics: the non-infective mutilated cases will not be dealt with by either of these institutions, as they are not so dangerous as to justify the expenditure involved by treatment and segregation. The method of dealing with these is not discussed, presumably the old-fashioned leper asylums will be sufficient to deal with them. Children born to leprosy persons should be separated at once from their parents at the earliest possible moment and sent to live with healthy relatives, so that they can be given a good prospect of escaping from the disease.

In the third lecture the treatment of the disease is discussed and emphasis is laid on the difficulty of estimating the effect of any special line of treatment. This arises from the extreme variability in the severity of the disease and in its tendency to spontaneous remissions and exacerbations. There are nearly as many "cures" for leprosy as for tuberculosis. Mercury, antimony and arsenic have been advocated, iodides and iodoform have met with some measure of success. Vaccines have had their triumphs, nastin and leprolin have resulted in temporary successes, but the derivatives of chaulmoogra oil and the crude oil itself now hold the field as the most promising remedies for the disease. The part played by Sir Leonard in developing the use of this valuable indigenous drug is well known to our readers, but the account given in the lecture should be read by every one who is interested in the leprosy problem. Great emphasis is laid on the importance of early treatment, as it is the recent cases which show the most rapid improvement and the largest percentage of clinical cures. Associated with this is the necessity for early diagnosis. Muir believes that the disease can almost always be detected

long before it becomes infectious, and he very strongly advocates the establishment of leprosy clinics on the lines on which he is working with such success at the Calcutta School of Tropical Medicine.

The prospect of permanent freedom from active signs of the disease is believed to be much greater than in tuberculosis. The last words of the lectures are, "the evidence that the treatment actually leads to destruction of the lepra bacillus in the body not only places it in a more hopeful position than the building up of the resisting powers of the tissues by the sanatorium treatment of tuberculosis, but also raises the still more important question of the possibility of applying the new line of treatment to the white man's scourge, tuberculosis." The most sceptical must admit that the outlook on the great scourge, leprosy, has been revolutionized by the genius and enthusiasm of Sir Leonard Rogers. It is legitimate and reasonable to maintain a critical attitude towards the exaggerated claims that have been made by some of the propagandists of the modern methods of treatment. It is equally unreasonable and unscientific to adopt the pessimistic attitude which prevailed up till a few years ago, and to tell the victim of leprosy that we can do nothing for him.

The value of the newer treatment is too firmly established to admit of doubt, and while some of us believe that a large share of the success is due to the improved hygienic conditions which are part of the system of every good leprosy doctor, and to the stimulating effect of the hope that is instilled into him, the results that have been obtained should convince the most conservative that leprosy is a disease which is amenable to treatment; it is a disease which every doctor in India should be competent to treat with confidence and success.

All cases will not be cured, there may even be some failures, but taking the disease as a whole it will yield a far larger proportion of successes than the sister disease tuberculosis, towards which we have always rightly encouraged ourselves to adopt a hopeful attitude.

When the medical profession and the general public have learned the lesson that leprosy will yield to prompt and energetic treatment and that the disease is one of the controllable infections, progress will be rapid. The profession is still far too much imbued with the paralysing belief that leprosy is incurable, too often the patient is told that we can do nothing for him: he "asks for bread and is given a stone."

In every medical school and college there should be a course of lectures and demonstrations on the diagnosis and treatment of leprosy by a teacher who has an intimate practical knowledge of the disease. Until the teachers themselves are taught the medical profession cannot be expected to have sound views on the subject of leprosy.

J. W. D. M.

THE POSITION OF INDIAN I. M. S. OFFICERS UNDER THE LEE COMMISSION PROPOSALS.

The *Gazette of India* containing the details of the recommendations of the Lee Commission accepted by Government has recently been published. One curious point in these rules is that, although free passages to England and back have been allowed to members of the Indian Civil Service of Asiatic domicile and to their families, Indian members of the other superior civil services, including those of the I. M. S., have been debarred from this privilege. It is obviously very important that Indian members of the technical services should keep themselves abreast of modern developments in their subjects, and this can only be done by occasional visits to England. We hope that Government will see their way to extending the privilege of free passages to Indian officers of the Indian Medical Service. Such a step would be to the advantage of Government, and would make for increased efficiency in the service. The extra expense incurred would be very small in comparison with the benefits which would result.

A Mirror of Hospital Practice.

A USEFUL METHOD OF ADAPTING AN ARTIFICIAL EYE TO A NORMAL OR RE-CONSTRUCTED SOCKET.

By R. E. WRIGHT,

MAJOR, I.M.S.,

Superintendent, Government Ophthalmic Hospital, Madras.

Most ophthalmologists practising in India have had difficulty at some time or other in obtaining suitable glass eyes for patients. This depends largely on the local conditions determining the available supply of these articles. The bulk of artificial eyes supplied to the retail opticians in India are manufactured outside India, and when it is necessary to fit a patient with a prothesis, the stock of the optician has to be gone through in order to find something as nearly suitable as possible. Frequently one finds that the bulk of the stock consists of single shell specimens which are not to be recommended at all. Having excluded these, one next finds that the balance—the double shell or Snellen reform eyes—are for the most part made with light coloured irides. In the case of a patient with light coloured irides there is some chance of a match. The few remaining double shell eyes, however, which have brown irides give one very little choice as regards the shade of brown, size of cornea and pupil, general size and shape, so that one may have the trouble of going through anything up to 500 or 600 specimens,

only to meet with disappointment. One cannot, except in rare cases, send the patient to the manufacturers. Under these circumstances one is frequently obliged to make shift with a shell too big or too small, or if the right size be luckily obtained, of quite the wrong colour. One is, indeed, fortunate if the right size is procured, for this makes it possible to preserve the socket in a suitable state till by a lucky chance the correct article is found. Patients, who cannot get a double shell of approximate colour and size, frequently resort to wearing a single shell which seems to them more suitable. In the end this gives rise to trouble, and as often as not a contracted socket is the result. This opens up the question of dealing with the contracted socket. It was in the past notoriously difficult to adapt a contracted socket for the reception of a prosthesis by plastic operation. The number of operative procedures designed to this end bears witness to the fact. The war fortunately gave a great stimulus to the plastic surgery of abnormal sockets, and now we have the method of epithelial inlays well established. Gillies in London, and Wheeler in New York, and others on the continent of Europe, have added greatly to our knowledge in this direction, so that at present one can undertake the planting of a suitable epithelial graft wrapped round a mould, in a freshly made pocket in the orbital tissues. With care these grafts always take, and a pocket of the desired shape and size is formed, suitable for the reception of a prosthesis. One cannot, however, cater for the standard glass eye, and so it becomes necessary for such sockets to be suitably "fitted." In these cases one is faced with an even greater difficulty in India than in the case of the normal socket, because the new socket is more irregular, and if it is not filled, it tends to contract and all one's labour is in vain. In hospital practice in Madras up till recently the number of glass eyes supplied was comparatively small, chiefly because the average patient is very loth to have an eye-ball removed, even though the procedure is surgically advisable, and also on account of the expense of artificial glass eyes. Nowadays, however, Indian patients of the hospital class and of the better classes too, desire more and more to have glass eyes and it is desirable that there should be some way of obtaining suitable shells from manufacturers abroad; and also that, till reliable manufacturers are established in India, there should be a simple way of preserving the socket pending the receipt of the required article. Formerly, if a suitable prosthesis was not available locally, the method of taking a plaster cast of the socket was available, but this is a difficult and not altogether satisfactory procedure. Should a suitable cast be obtained, it had the position

and size of the cornea marked upon it, the size of the pupil noted, and the cast, together with the shade of iris required was forwarded either to an optician holding a large stock for matching or to manufacturers abroad. In the case of a re-constructed socket even this method is denied to the surgeon, for by the time the model is copied, the copy is no longer suited to the socket.

Having been faced with these difficulties over and over again, I tried to come to some arrangement with a well-known manufacturer in London to supply me with a series of standard shapes and sizes, a duplicate of which he should keep; and also a set of 24 different shades of brown of which he should retain matches. I hoped in this way to be able to quote him a certain number for size and shape and another number for shade of iris, giving actual measurements for cornea, pupil and position of cornea and allow him to blow a suitable double shell. He did not consider this a practical procedure and so negotiations broke down. Recently, having had to cater for the needs of a series of patients in whom I had re-constructed the socket by means of epithelial inlays, I tried modelling shells out of dental stent and covering them evenly with hard paraffin by dipping. The stent gradually altered shape at body temperature and so proved useless. The experiment, however, suggested modelling in paraffin and this proved highly successful. After numerous steps, which need not be recorded, a definite plan has been arrived at, as follows.

An approximate model is cut out of a solid uniform block of paraffin of 60° melting point, free from bubbles, such as may be obtained from a laboratory. Care is taken to have it too big in all directions in the first instance. This is carefully whittled down with a scalpel, aided by the heated handle of a scalpel for hollowing out the back. All the peculiarities of the socket are gradually catered for till a good fit is obtained. Then if a more artistic effect is desired, the position of the cornea is marked in front whilst the paraffin shell is still in position. The shell is then removed and the corneal area countersunk. A piece of paper suitably coloured to the correct shade of the iris and cut to size is then soaked in hot paraffin and let into the depressed circle of the shell surface, made to adhere by the aid of a hot scalpel or needle, and embedded in position by running over it melted paraffin in drops from the end of a hot rod. Care must be taken to avoid bubbles. Anyone familiar with embedding of tissues will quickly grasp the idea. A black spot may be painted in the first instance in the middle of the paper iris, or better still a suitable black glass bead is laid on its centre, before the heated paraffin is dropped on to form the cornea. Having suitably rounded and

smoothed off the corneal area, the work is complete. The shell tends to become more translucent with use. A plaster cast of this paraffin shell is now made so that others can be supplied, if required. The paraffin shell is apparently non-irritating and beautifully smooth, it retains its shape well, certainly for several months and probably much longer. This procedure enables one to give the patient at once a moderately reasonable appearance, maintain his socket in good order, and at the same time to send away an accurate model with the necessary details to enable the manufacturer to construct a suitable prosthesis.

TWO INTERESTING CASES OF POST-TYPHOID SEQUELÆ.

By Dr. A. BAYLEY DE CASTRO,

Junior Medical Officer, Haddo, Port Blair.

THE following two cases of post-enteric complications are, I think, of sufficient interest to justify publication. They are also far from being common sequelæ.

Case No. 1.—The first was a case of a left parotid abscess in a female patient. Her history was of fever of a month's duration with a persistent diarrhœa of loose yellow motions, constant headache, anorexia, and a feeling of extreme lassitude. The first period of her illness was characterised by high fever, and for four days, as stated by the relatives, she had been delirious. Five days before coming into hospital the temperature again started to rise, and the left side of the face swelled up.

The patient on admission (12th September, 1924), was in a very low condition, and also presented an extreme degree of emaciation. The tongue was encrusted with a hard, dry, brown deposit, and sordes were present on the lips and teeth. The breath was foul, pulse weak and thready, and during sleep subsultus tendinum could be detected. The swelling on the side of the face was hard and brawny, with a small fluctuating area between the angle of the jaw and the ear on the left side. The urine was turbid and had a trace of albumen. Nothing was ever detected in the lungs, and the heart, although weak, was normal in rhythm. The Widal reaction was + 1 in 20 to *B. typhosus*; while Marris' atropine test was also positive. This is a point worthy of note, indicating the possible value of the test at a much later date than that advocated, or if we take a 1 in 20 dilution to be so very weak as to lead to the exclusion of typhoid, then the atropine test can be stated to be positive in other infections besides typhoid.

Two days after admission the abscess pointed sufficiently to call for surgical interference, and a few days after the patient started to recuperate and was finally discharged from hospital on the 9th October, 1924.

Case No. 2.—The second case, which unfortunately proved fatal, was that of an abscess of the spleen following a long and protracted course of enteric fever.

The patient was a young Burman of 25 years who before admission to hospital for paratyphoid A. on 1st September, 1924, had had the following previous admissions; for malaria 4, indigestion 1, climatic bubo 1.

On the day of his last admission he presented a very lethargic expression, looked weak, had a small pulse and an enlarged spleen and liver, the former being one inch below the umbilicus, and the latter $\frac{1}{2}$ inch below the right costal border. His temperature for the first four days was of malarial type, but after that assumed

a step-ladder character, and with this the pulse showed a disproportion to the temperature. No malarial parasites were found in the blood. On the 10th day of illness Marris' test was performed and found to be strongly positive, and on the 14th day the Widal reaction was positive to paratyphoid A up to a dilution of 1 in 120. By now a very typical and persistent diarrhœa had set in, and the patient was getting weaker daily. On the 23rd day of illness the temperature had come to normal, and after that assumed a remittent character. No bronchial symptoms ever developed, anorexia was replaced by hunger, but digestion was so very poor that no solid food of any kind could be given. The hepatic enlargement had by now disappeared, but not so the enlargement of the spleen, which was very tender to palpation. On the 2nd October, 1924, the temperature again started to rise up to 102° in the evenings and 100° in the mornings, and the patient started to emaciate rapidly. A blood count showed 78 per cent. of polymorphs. On the 10th October the slightest and lightest palpation of the spleen elicited excruciating pain and the patient's expression began to become pinched, whilst a dilatation of the left ventricle of the heart was also detected. A total leucocyte count gave only 7238 per c.cm., and the hæmoglobin index was 45 per cent. On the 12th an exploring needle was put into the spleen but no pus struck, for reasons to be explained later; and this disappointed me much as I was very sanguine of the diagnosis by now. The little exploring caused a good deal of collapse. By evening the patient had become delirious, pulse 156, fast and small, and at 4 p.m. on the 13th he died.

I shall only touch on the most noticeable features of the post-mortem examination as regards the spleen. This organ was firmly bound down on all sides by dense and strong adhesions. When removed it weighed 4½ lbs., and was 9 inches in depth. This explains why the exploring needle never entered the abscess cavity which was situated at the hilum and extended backwards. The part of the organ not affected by the abscess formation was a solid, hard, fibrous mass.

These two cases constitute the first two of abscess-formation following enteric fever which I have encountered in my experience of very many years.

AN UNUSUAL CASE OF MALARIA.

By V. N. DEUSKAR, L.C.P. & S., I.M.D.,
Indian Station Hospital, Ahmedabad.

At 2 p.m. on the 14th September, 1924, I was called to attend a patient suffering from severe abdominal pain. She was a strong, well-built Punjabi lady, aged 26, and not pregnant. She had been in good health until 10 a.m. that morning, but when seen was suffering from restlessness and severe abdominal colic. The onset of illness had been sudden, with vomiting and pain in the epigastrium and hypochondrium. Constipation was present, but the severity of the pain was out of all proportion to the degree of constipation present.

She stated that seven years previously she had had an exactly similar attack with urticarial rashes all over the body, which had lasted for a day and had then been relieved by injections. She was certain that this rash would recur. Her temperature was 100.2°, pulse 100, respiration rate 20.

A hypodermic of morphia was given at once, followed by an ounce of castor oil and a hot water bottle locally. She passed two good motions subsequently, and by the evening was in a comfortable condition.

On the 15th September I was again called in at noon, as the symptoms had all recurred. Severe colic had set in at 11 a.m., whilst the patient was covered from head to foot with an urticarial rash, with intense itching and burning sensations. The temperature was 100.2°, pulse 108, respiration rate 20. Thorough examination failed to reveal the cause of the colic, and the abdomen was perfectly soft and not rigid anywhere. No signs of disease could be elicited in the chest, whilst renal colic was out of the question. I had to be content with a diagnosis of gastric neuralgia, and gave morphia, a sinapism, together with calcium chloride and magnesium sulphate for the urticaria.

dramatic. The rash disappeared during the night, whilst there was no recurrence of the colic the next day. The patient was subsequently put on to euquinine, 30 grs. daily for one week, followed by 10 grs. daily for two months, and by the 18th September was in good health.

The interesting features of the case are, first the rash,—this being the first instance in which I have seen an urticarial rash associated with malaria; secondly, the severe and intense abdominal colic, which confused the diagnosis, but which yielded at once to quinine administration; thirdly, the very marked quotidian recurrence of the symptoms, so characteristic of malarial neuralgias. Fourthly, and most important of all, the necessity for routine examination of the blood in all cases of fever of undiagnosed origin, no matter what the cardinal symptoms and the temperature chart may be. The chart in this case was as appended. To quote

TEMPERATURE CHART.

By the evening she was again in a condition of comfort.

The next day, I was surprised to be again called in to see the patient at almost the same hour. Her symptoms were again as before, but, in addition, there was much pre-cordial distress. Not knowing what to do, I called in Capt. F. Griffith, I.M.S., D.T.M. (Cal.), officer commanding the Indian Station Hospital, Ahmedabad, who suggested examination of the blood.

On examination of stained blood films a mixed infection with benign and malignant tertian malaria was found, the former parasite being found in all its phases of schizogony. A differential count of the leucocytes shewed 55 per cent. of mononuclears.

The diagnosis having thus been established, I gave 8 grs. of quinine intramuscularly the same evening, followed by 30 grs. of quinine in solution the next day, the first 20 grains being taken before 11 a.m. The result was

from the editorial in the *Indian Medical Gazette* for last July, on "The Seven Scourges of India"; "the diagnosis of malaria depends, not upon the whim of the physician, nor upon 'clinical' tests by the administration of quinine, but upon finding the parasites concerned in blood films taken from the patient."

STRICTURE OF THE ILEO-CÆCAL VALVE, AND HYPERPLASIA OF THE CÆCUM FROM TUBERCULOSIS.

By ERNEST F. NEVE, M.D., F.R.C.S.E.,
Senior Surgeon, Kashmir Mission Hospital, Srinagar.

Mrs. V. M., a Hindu lady, aet. 30, was admitted on June 6th, 1924, suffering from pain in the right iliac region. There was a history of diarrhoea and occasional vomiting. Owing to this and the pain after meals she was living on a greatly reduced diet. On examination a movable tumour, hard and tender on pressure, was found in the right iliac region.

Without any preliminary treatment, a 4 inch Battle's incision was made. This revealed a matted mass of adhesions round the cæcum, which was a solid mass about the size of an orange. After separating adhesions I resected the cæcum and did lateral anastomosis of the ileum to the lower end of the ascending colon. The operation was greatly facilitated by the emptiness of the ileum, which was remarkable as there was almost complete obstruction. The cæcum consisted of a mass of fibrous tissue. The cavity was almost obliterated. There were signs of old ulceration and a small aperture like the slit in a child's money box indicated the position of the contracted rigid ileo-cæcal valve.

There were numerous enlarged mesenteric glands and unmistakable evidence of local tubercular peritonitis.

The patient made a good recovery. The temperature was normal on the second day, rising in the evening to 100.2° , with a pulse of 100. It was 96° before the operation. After the 6th day there was no evening rise of temperature and the patient was dismissed on June 30th quite convalescent.

Remarks.—This is the second case of the kind which I have seen. The first, seen by me in consultation when travelling in India, I advised to go home, where she was operated upon by a well known surgeon, who, basing his opinion on a pathologist's report, wrote to me, after excising the cæcum, saying that he feared the case was malignant. The lady is alive and quite well more than ten years after this verdict was passed!

It is important in these cases to have an empty bowel if possible. Lateral anastomosis, although taking twice as long, is I think more secure. In any case reinforcement with omentum is wise.

TWO CASES OF TUMOUR OF THE OVARY.

By S. C. DAS GUPTA, L.M.S. (Cal.),
Senior Surgeon, Bir Hospital, Katmandu, Nepal.

THOUGH ovarian tumours are not very common here, yet I have recently seen two cases of ovarian tumour of very large size, within four weeks.

Case 1.—Hindu female, aged 35, mother of three children, gave a history of one year's duration of the growth. For nearly a year she had been regarded by her relatives as pregnant, but as she gave no signs of delivery at the expected period, she was brought to hospital. The growth had first appeared on the left side and had gradually filled the abdominal cavity. On examination, there was a hard, solid mass in the left lumbar region, a dull percussion note both in front and in the flanks, resistant bulging in the left lateral fornix, with sinistro-flexion and non-enlargement of the uterus.

On opening the abdomen a large quantity of thick mucilaginous fluid poured out, and the tumour had to be tapped in order to reduce its volume prior to delivery. The adhesions were few and soft, and the pedicle gave no trouble. The patient made an uneventful recovery

and was discharged from hospital five weeks later. I heard subsequently that she gave birth to a healthy

CASE 1.—After operation.

CASE 2.—Before operation.

child 13 months after the operation. On section, the tumour proved to be a cysto-adenoma with several cavities inside filled with a clear, semi-solid gelatinous fluid. Photograph No. I shows the patient after recovery, with the removed tumour beside her.

Case 2.—Hindu female, aged 27, nullipara, gave a history of a gradually increasing painful swelling of about four years' duration. She was extremely weak and emaciated and could not even walk a few steps without support. The abdomen was uniformly enlarged, but the portion below the umbilicus appeared the most prominent. The percussion note was dull everywhere,

CASE 2.—After operation.

and a thrill was palpable at the sides and even at the posterior fornix per vaginam. On bimanual examination neither the uterus nor ovaries could be felt.

Operation necessitated a preliminary tapping of the cyst, and a huge unilocular cyst was disclosed, filling up the whole of the abdomen and going down into the pelvic floor. Incision from the xiphoid to the symphysis pubis was necessary, and the cyst was adherent on all sides and to almost every organ in the abdomen, the adhesions being strong and vascular. The omentum was adherent and bits of it had to be removed with the tumour, which was also adherent to the sigmoid flexure, the caecum, appendix and posterior portion of the uterus. During the extensive dissection which resulted, a gushing sound became audible, synchronous with inspiration, and it was discovered that this was due to entrance of air through a minute tear in Douglas' pouch. The vagina, which had been douched prior to operation, was therefore packed with moist iodoform gauze.

Twice during operation the patient almost collapsed, and 1 c.c. of pituitrin was given on both occasions, whilst two pints of normal saline were given intravenously. After closing the abdomen, the patient was kept in Fowler's position for six days, and regularly catheterised for three days. There was a good deal of pain, and morphia had to be given. The wound healed by first intention, and the patient left hospital six weeks later. Photographs Nos. II and III shew the patient before and after operation; in the latter the removed tumour is shewn resting on a basin beside the patient.

A CASE OF STRANGULATED HERNIA.

By SHAMBHU NATH MISRA, RAI BAHADUR,
Civil Surgeon, Bulandshahr.

An old man of 92 years of age, Mahomedan by caste, came to hospital at about 10 a.m. on the 22nd September, with the following complaints:—

(1) Hiccough. (2) Vomiting. (3) Having passed no motion or gas for the last five days. (4) Extreme excruciating pain in a small melon-like tumour over the right inguinal region. This was hard, irreducible, dull on percussion and hot. On enquiry it was found that he had been subject to right inguinal reducible hernia for the past 20 years or so.

Present State.—The patient was a thin, weak, emaciated man with slightly coated moist tongue, temperature 100°F., pulse small and rapid, and 100 a minute. The bowels had not moved, nor had he passed any flatus; he had vomited bile several times, fortunately it was not stercoraceous. The patient and his relatives were informed of the nature and the gravity of his condition. It was decided to operate on him at once. Some time was spent in getting the necessary instruments and appliances sterilized; the patient was then put under chloroform and Bassini's operation was performed under full aseptic precautions, for assistance in which I am indebted to my Assistant Surgeon Sardar Chanan Singh Saheb.

The patient made an uneventful recovery with no rise of temperature and the wound united by first intention. The stitches were removed on the 10th day and the patient was discharged cured on the 14th day. The case is of interest in the following features:—

1. A very old man, practically in a moribund condition.

2. On cutting the strangulating band and opening the sac, the bowels were found cyanosed and much sanguineous exudate was found. The whole hernia was returned to the abdominal cavity and the parts were interfered with as little as possible. The sac was adherent in its lower segment and the adhesions were very strong and hence the adherent portion was left *in situ*. Luckily the whole of the exudate appears to have been absorbed and the bowels began to work, as the patient passed a motion and flatus just after coming round from the anæsthetic.

3. Hiccough continued for three days after the operation. Sodium bromide with chloral hydrate in homeopathic doses were administered and served the purpose very well.

4. For four days nothing but a little warm water was given to quench the thirst.

5. In this particular case, the patient was without nourishment in any form except water for ten complete days and on the 11th day he

was given a very little milk mixed with water and lots of fresh lime juice separately.

6. The above state of affairs shows clearly that, if surgery is properly done under strict aseptic precautions, one can save life, even in such advanced cases.

A CASE OF PULMONARY EMBOLISM.

By S. SERHACHAR,

Sub-Assistant Surgeon, Mulbagal, Mysore State.

THE patient, a woman aged about 27 years, had a normal labour of about five hours' duration. The puerperim was quite normal, with no rise of temperature, no sepsis, and the lochia were healthy; but the uterus did not appear to involute properly, and on the seventh day the fundus was still palpable just below the level of the umbilicus. So, in addition to such other measures as adopting the completely recumbent posture and a firm binder, etc., an injection of 1 c.c. of "Hypoid" pituitrin was given hypodermically.

Within three minutes of the injection the patient began to cry out with intense and sudden pain of a stabbing character in the right side of the chest and back. She sat up in bed, complained of orthopnoea, became pale in the face and seemed terrified. The pulse, which had been of normal tension and 63 to the minute, now became irregular and reduced to 40 to the minute. After some 20 minutes of acute suffering she was spontaneously relieved of her agonising symptoms. Simultaneously with the commencement of the pain in the chest there was a discharge of bright red blood from the uterus, and clots were found on the diaper.

The whole of this day the patient felt weak and exhausted, but otherwise normal, and subsequently the uterus involuted rapidly.

One presumes that the sudden rise of blood pressure, following upon the injection, had dislodged clots occluding the orifices of some of the vessels in the uterine wall, and had caused air embolism of the right pulmonary artery. Possibly the dose of pituitrin given was too large, or it was too late in the puerperim to give such an injection?

A CASE OF TRAUMATIC PTOSIS.

By P. B. KARKAREY, M.B.,

Nagpur, C. P.

A BOY aged 15 years was brought to me for consultation, suffering from unilateral ptosis of the right eye, of duration of some 14 to 20 days. On examination of the affected eye, a linear scar was found, just on the supra-orbital ridge. This had been caused by a pet deer, which the boy had been feeding, and which raised its head and accidentally struck him near the inner canthus of the right eye.

The horn had slipped over the supraorbital ridge, causing a clean cut of the skin and the levator muscles. The cut had been treated by a local doctor in the village and had healed.

The parents were advised that operation—so far from doing good—might possibly do harm. As the patient insisted on treatment of some sort, however, silvol eye drops were prescribed, and he was instructed to massage the lids, and to make every effort to improve the tone of the injured muscle. He was told that the condition would probably become entirely cured with time.

Ten days later the ptosis was very much less, and later disappeared. My reasons for publishing this note are first to draw attention to trauma as a possible cause of unilateral ptosis—as I have not been able to find any reference to such a cause in the literature; and secondly to point out the fact that in such a case as this operation would probably have done more harm than good.

CALCIUM LACTATE, A PREVENTATIVE OF STILL-BIRTHS?

By DAVID PERERA,

Poonagalla Group Hospital, Koslanda, Ceylon.

WALLIAMMA, aged 32, the wife of a Kanakapulle on this estate, had given birth to eleven children, with the following histories:—

Her first child is a male of 14 years, still living.

The second, a male child, was born dead at the 9th month.

The third also had the same fate, at the same period.

The fourth, a female, was still-born at the 7th month.

The fifth, a female, is still living, and 8½ years of age.

The sixth, a male, is still living, and 7 years of age.

The seventh was a female, and died three months after birth.

The eighth was a male, still-born at the 9th month.

As she was then very anæmic and suffering from ankylostomiasis, at this period I treated the latter disease, and followed this up by a full course of iron tonics.

The ninth child, however, was also still-born at the 8th month.

The tenth child, a male, was still-born at the 9th month.

When she became pregnant for the twelfth time, I gave calcium lactate, 10 grains twice daily, from the 6th month of pregnancy until the birth of the child. The patient stated that her general health in this pregnancy was far better than ever before, and she gave birth to a healthy female baby on the 5th September, 1924, without even the assistance

of a midwife. The child is still living and in good health, though small in size. The mother is also in good health, but as the maternal milk is deficient, the child is being reared on cow's milk.

SPECIAL ARTICLE.

RECOLLECTIONS OF THE CALCUTTA MEDICAL COLLEGE FORTY-FIVE YEARS AGO.

By an OLD MILITARY MEDICAL STUDENT.

The death of our beloved professor Colonel Kenneth McLeod, reported last year by the *Statesman*, carries one's memory back across a gap of nearly fifty years to the Calcutta Medical College of those days.

The revolutionary changes which medicine and surgery have undergone within my recollection have been accompanied by such changes in the manners and customs of Europeans in Calcutta, that I hope that these rather disconnected reminiscences may not be devoid of interest to the present generation.

Buildings.—The hospital buildings have changed less than might have been expected. There was only the stately old pile which stands to-day and in it all the patients, medical, surgical and obstetric, European and Indian, were housed. To the north of it was a lawn, where the Ezra and Eye Hospitals now stand and to the south was the students' playground as at present. The quarters of the Principal and Resident Medical officers are still the same and the apothecary, as he was then called, lives where he did in my time. The old museum stood on the site occupied by the present building, but nothing now remains of the former Medical School buildings. To the west of the Principal's quarters stood the two lecture theatres and next to them was the Chemical Examiner's laboratory, a long single storey building. Still further west was the military students' range and the Police Mortuary, adjoining Coisootia Street. The Eye Hospital was on the latter road and the Eden was being built, as was Chuni Lall Seal's Dispensary.

Initiation.—The session used to begin on the 15th June and I joined as a military student in the year 1880. I was cordially received by the older students in the military students' range, which stood on the site now occupied by the Pathological Department. I was given a hearty breakfast, doubtless to disarm any suspicions I might have as to what awaited me. After this two stalwart students armed with thigh bones conducted me before a tribunal seated round a table, under which I spied a heap of boots and shoes and an enema syringe. I was asked many questions, but the most important one was whether I was willing to pay my footing of Rs. 4 and abide by the established rules of the students' range. On giving my assent, I was congratulated and marched out, but woe betide the bold freshmen who refused. Our students' tribunal, like that of the Holy Inquisition, understood the moral effect produced by an examination conducted in sight of the instruments of torture, and the horrid suggestion conveyed by the articles I had glimpsed under the table doubtless helped many a timid one to make up his mind. If still recalcitrant, the tribunal was quite prepared to resort to extreme measures in the interests of discipline.

The major portion of the footing money went to a fund for starting a gymnasium, but a small fraction provided refreshments for the celebration which took place when all the new students had joined. This consisted of an afternoon "at home." Every freshman had to sing a song or make a speech, standing barefooted on a table whilst two students beat time on his toes with the heels of boots. The less the song or speech was

appreciated, the harder and faster the beating of time on his toes went on, until a sudden drop off the table on to the floor signified that the audience had had enough. Nevertheless, the freshman was held to have qualified to enter the ranks of the military medico's fraternity.

The Staff.—The composition of the teaching staff has not changed materially. The number of professorships held by I.M.S. officers was the same as now, with the exception of the professorship of pathology, which was then held as a collateral charge by the Resident Physician. Dr. John Martin Coates, whose death under tragic circumstances will be referred to later, was the Principal and Professor of Medicine. Dr. Kenneth McLeod was the Professor of Surgery and Dr. Daniel O'Connell Raye was Second Surgeon and Professor of Anatomy. Midwifery was taught by Dr. Charles and later by Dr. Harvey, who afterwards became Director-General, I.M.S., whilst Dr. R. C. Chandra was Professor of Materia Medica. These were the most notable members of a staff, all of whom have left reputations likely to endure for long in India. Their portraits, in the costume of a bye-gone generation of medical men, adorned in many cases with luxuriant beards or "Dundreary weepers" still hang in the professors' room at the Medical College.

In addition there were two demonstrators of anatomy and the usual staff of house surgeons and house physicians. The apothecary, the dispensary officer and the obstetric house surgeon were members of the I.M.D.

There were two European sergeants, Connolly and LeMott. The former was in charge of the instruments, and the latter who, though small in stature, had the heart of a lion, was responsible for the maintenance of discipline amongst the patients, no light task when, as often happened, he had a "rough house" of drunken sailors to handle. He carried a bludgeon as big as himself and superintended the treatment of alcoholic cases. This process was simple but efficacious, a blistic poured water over the patient from a height out in the open, and whether it was the soothing influence of the cold water or the menacing flourish of his baton which effected the cure I am not prepared to say, but I do know that this little bantam never failed to reduce the most obstreperous Jack Tar to submission.

Then there was the European matron, Mrs. Bowler, who presided over the maternity ward, and last but not least the nurses. These latter were portly dames of mature years, who wore no uniform, but carried a fan as a badge of office. They underwent no regular training and passed no examinations; all that came later with the advent of the Clewer sisters. They picked up their work somehow and their main duty was to oversee the ward servants. Many of them were comely enough and I well remember one youthful widow who was a veritable magnet to the susceptible military students.

The Wards.—The First and Second Surgeons were in charge of a ward each of Europeans and Indians, likewise the First and Second Physicians. There was one ward for maternity cases in the upper storey to the extreme west under the Professor of Midwifery. Each of these five professors had a passed student of the College as house surgeon or physician. The accident ward was under the main staircase and occasionally cholera cases were admitted to it, but they, poor wretches, did not trouble us for long; there were no saline injections in those days and all but the mildest cases were soon claimed by the undertaker. The operating theatre was on the first floor and next to it was the instrument room, where dwelt Connolly, who put in most of his time cleaning and polishing the instruments, an easier task in those days than it is now. He had not to contend with the corroding and blunting action of boiling water, and his shining razor-edged knives were a joy to see and to handle, which is denied to the modern surgeon. The dispensary was in the basement facing south, and the present flight of steps on that side did not exist. Small-pox cases all went to the Campbell

Hospital, which had been started a few years before to accommodate them, and plague was non-existent in those days.

In the medical wards the days of bleeding and drastic purging had passed, and except for the absence of clinical pathology, of vaccines, sera, of synthetic preparations with outlandish names and of endocrine therapy, the work did not differ greatly from that of the present day. But in the surgical wards what a difference! Aseptic surgery was as yet unborn and the use of antiseptics was still in its infancy. Wire baskets filled with lumps of charcoal were suspended in all the wards and were supposed to act as germicides, deodorants and miasma absorbers. We spoke of "laudable" pus in those days and saw it too, for practically all major operation cases suppurred freely. Our two exponents of surgery, of whom one hailed from bonnie Scotland and the other from the emerald isle, were at variance with each other over this question. The Second Surgeon had no faith in Lord Lister's doctrine, whilst the Professor of Surgery was an ardent convert. The method was so simple and convenient. It consisted of spraying carbolic lotion by means of a hand spray resembling a lady's scent spray in the near vicinity of the part which was being operated on or dressed. Later a spray worked by steam was used for operations and distributed the lotion over a wider area. The idea was to purify the germ laden air around the part. We did not have all the trouble of sterilising the patient's skin and the surgeon's hands, nor the complicated ritual for the preparation of instruments, ligatures and dressings which the student of to-day has to master. Undreamt of too were the ghost-like objects with cap, mask, gown and gloves who now move delicately about the theatre with hands uplifted for fear they touch anything unclean. We just took off our coats, rolled up our shirt sleeves, washed our hands and were ready for anything from threading needles to lifting the patient. We only clipped our nails when they got so long that we hurt our fingers when percussing, unless social convention demanded that the operation was performed oftener. The effect of the spray was wonderful. When we had yard upon yard of pus-laden bandages and dressings to remove, or when pus poured out of a pocket in a stump bringing the sutures away with it, we believed that the system was being purged of effete matter, which was better out than in, and so long as the granulations at the end of the stump were nice and pink, we were taught that all was well. Comforting as this was, it did nothing to palliate the offence to one's olfactory organ and we often used to wonder why, if Nature could sometimes heal a wound without all this unpleasant smell, she could not always do so. The spray was brought into use and acted like magic. It was not certain on what it acted, but what we did know was that we did not have to hold our noses when we went into the professor's wards, as we had to in those controlled by the exponent from the emerald isle. The latter was no believer in sprays and still relied on the virtues of the charcoal baskets, but even we were beginning to lose faith in them, and the contrast in the odours of the two sets of wards shook our faith in what he taught us.

Surgery in those glorious days was delightfully easy and we disposed of a dozen cases in the time taken by the present-day surgeon over one. For instance, if a surgeon saw a man waddle into the surgical out-patient room with something dangling between his legs like a sporran, diagnosis and treatment followed swiftly. A grab was made at the tumour while the patient was trying to explain, a trocar was plunged in, fluid evacuated, iodine or carbolic acid injected, the sac well shaken up and the puncture given a hard pinch to seal the hole, all in less time than it takes to tell. The patient went on his way rejoicing at the restoration to usefulness of an organ which he had not caught sight of for some time and spread abroad the fame of the hospital where a radical (?) cure had been effected so speedily. Acupuncture was in fashion in those days

and sometimes effected equally dramatic cures. I have seen a patient brought in crippled with sciatica, who took up his bed and walked after a long needle had been plunged into the sciatic nerve and left there for half an hour.

The scope of the operative work was of course much more limited then. The only abdominal operation I ever saw was the removal of an ovarian cyst performed by Dr. Harvey, which was said to have been the first ever attempted in India. The patient died and at the post-mortem examination next day internal hæmorrhage was found to have been the cause of death. Another case was brought on to the operating table, but just as the operation was about to begin it was decided that the tumour was an enlarged spleen and therefore better left alone. I also remember seeing a large cyst tapped by the vaginal route. Colonel McLeod's strong points were hernia, stone in the bladder and scrotal tumour, the latter sometimes nearly as big as the patient and taking months to heal by granulation. He improved on Wood's old operation for hernia and his cases did not recur. I remember one case of cancer, for which he removed the tongue and most of the lower jaw. The man could not speak, so a reed with a slot in the middle was inserted, which enabled him to mumble in a monotone. Mr. Woods, the dentist, made him an artificial jaw of silver, which was a great success, but the rascal sold it and came back for another—which needless to say he did not get. There were no Sisters or special nurses to fuss around the patient and tell him how brave he had been. No, this was men's work, and females were regarded as out of place in the operating theatre, as they were supposed to be likely to scream or faint at the dreadful sights.

McLeod was a clean, quick operator, always ready to act promptly in an emergency. His students had to anticipate his wants at operations and carry out orders at the double. He was one of the pioneers of antiseptic surgery in India and was a born teacher and ruler of men. Tall and strikingly handsome, with a ready smile for a student and a kindly sympathetic manner, even if sometimes sarcastic, he was always the dignified, courteous gentleman, who could command respect and obedience from the most turbulent class. He was a fluent, witty speaker, whose name was always on the toast list at the St. Andrew's dinner. His memory was remarkable, he knew all his students by name and studied their interests. At a lecture a student once drew a caricature of him; his watchful eye noticed the diversion, the student was called up and the picture examined. With a quiet smile he said "highly artistic, but not surgical." Such was Kenneth McLeod. His portrait in the Medical College is a speaking likeness, his vigorous personality is written on every line of the handsome face and it is no wonder that he inspired such affection in his students, an affection which endured long after they had left the College.

Manners and Customs.—The Britons of those days were tough fellows who defied sun and rain in their service of the conventions. The professors always appeared in dark suits and small bowler hats and one of them was never out of a morning coat, which was always considered the correct costume for lecturing. Stiff starched shirts and collars were worn at all times, regardless of the heat and often necessitated three or four changes of shirts in a day. Tall hats and frock coats were *de rigueur* at church, in the Eden Gardens and at all fashionable gatherings, a custom which has only lately died out and even now is still observed by certain very exalted officials. The light suits and soft shirts of the present-day would have been regarded as most unbecoming and unprofessional, and I shudder to think of what would have been said to the proposal recently put forward that shorts and shirts should be the day wear for business men.

The horse was the only means of conveyance, but in those days there were no phaetons available for hire, the only public carriages were second and third class

bund-gharries and *palkies* carried by four bearers. The well-to-do doctor was known by his brougham and pair of horses, and the stable which a busy man had to keep up was prodigious. One professor had a miniature caravan in the form of a brougham, with relays of a dozen or more pairs of horses at different parts of the town. If a conveyance came thundering down on you in the street like the present-day fire brigade, with two lusty syces roaring warning to the unwary pedestrian, you knew it was the Professor of Midwifery going to a case, and jumped aside to let him pass. Doctors were not proud in those days and did not disdain to use the humble third class *tikka-gharry* when summoned in haste to a case. I was walking quietly along one day, when a *gharry* approached me at top speed, the *Jehu* urging his steeds with whip, rein and tongue. Round the corner it came at such an angle that it would surely have overturned, had it not been steadied by the weight of three portly semi-nude gentlemen seated inside it. As it flashed past, I saw wedged in amongst the occupants with his legs dangling out of the window, a figure with a grave face and a bundle of papers under one arm. It was the Principal, Dr. Coates, going to an urgent case. This professor too loved his "*la-ads*" and was beloved of them. He had hardly retired to enjoy a well-earned rest when the wires flashed a message across the seas from a *rani*, an old patient, to come. He came, but at what a cost: the case over, he was on the point of returning to England, when he fell a victim to cholera and died in Sealdah House, the residence of his son-in-law, Dr. Gibbons.

Recreations were scanty in the eighties, badminton was the only game played, and riding or driving on the Red Road or walking in the Eden Gardens appropriately attired were the usual relaxations. We students often used to go there in the evenings and one familiar figure on the famous Red Road is recalled to my memory whenever I go there. A smart lady on a spirited mount, followed by a sumptuous barouche and pair, in which sits a courtly and courteous gentleman, who does not disdain to return the humble salutation of a student. It is Dr. Chandra, the Second Physician and one of the first Bengalees to be appointed to the staff of the Medical College.

Hardly less popular than Dr. McLeod was Dr. O'Connell Raye, the Professor of Anatomy and Second Surgeon. Spare and of medium height, always very smartly dressed in the height of fashion and never without a flower in his buttonhole, he was a complete contrast in appearance and in every other way to McLeod. His manner was quiet and unassuming, he was very patient and painstaking in his operations, and took endless trouble over the teaching of the students, with whom he was a great favourite.

Dr. Coull McKenzie, the Professor of Medical Jurisprudence and Superintendent of the Campbell Hospital, was another of the bushy-bearded ones who, like most lecturers on that subject, had a great fund of highly flavoured anecdotes. They were all good fellows. Here's to their memories!

Current Topics.

Chlorine Inhalation in Respiratory Infections.

Much attention has been given to chlorine as a remedy for respiratory infections.

Vedder and Sawyer liberate 146 c.c. of chlorine in a room of 1,000 cubic feet; after half an hour liberate 500 c.c.; again after three quarters of an hour they liberate 250 c.c.

The chlorine is discharged from a small cylinder of liquid chlorine, the gas being measured by passing it

through a glass cylinder filled with salt solution. The gas is discharged in successive amounts of 30 c.c.

The patient inhales the chlorine for an hour. Colds, influenza, etc., have been treated with great success.

Immunity against Malaria.

LIEUT.-COLONEL S. R. CHRISTOPHERS, I.M.S., has a very important article on this subject in the *Indian Journal of Medical Research* for October, 1924. This should be read by all who are interested in malaria. The conditions prevailing in a hyper-endemic area in Singbhum District were closely studied and it was found that while the percentage of infection was very high (87 to 100 per cent.) in persons resident from one to ten years in the area, there was a great variation in the intensity of the infection and of the symptoms.

The parasites in indigenous infants and in non-immune new comers rapidly reached an average of over 10,000 per c.mm. after one year of residence and then fell to about 1,000 per c.mm. after three years. The higher counts of over 10,000 seldom persisted longer than two years. This period is called that of acute infestation and attack conditions of malaria are practically continuous. Then comes a period in which the parasites are much fewer, some degree of immunity is established, only occasional attacks occur, and this period is called that of immune infestation. In this stage a very high proportion of the children show parasites, so that the parasite index would indicate as high a prevalence of the disease as among the children in the period of acute infestation. This period of immune infestation goes on till adult life and the persons in this stage of infection are immune to severe malaria. New comers up to the age of five go through the same periods of infection as children born in the area, but after the age of five the new comers who were examined were not susceptible, possibly because of some degree of previously acquired immunity. The size of the spleen was not specially great during the period of acute infestation, averaging only about 5 cms. of projection beyond the costal margin, whereas in the period of immune infestation larger spleens were encountered and the average size remains much the same as in the period of acute infestation.

The number of crescents found in the blood was roughly in proportion to the number of asexual parasites, so that the children in the stage of acute infestation harboured a far larger number of crescents than the children and adults in the stage of immune infestation, the proportion found in the two groups being 2,095 against 132.

The aboriginal tribes showed no racial immunity, but when they live in hyper-endemic areas they become "salted" or immune after a period of intense infestation.

Intramuscular Injections of Quinine and Other Drugs.

(*Indian Journal of Medical Res.*, October, 1924).

MAJORS H. W. ACTON and R. N. CHOPRA, I.M.S., of the Calcutta School of Tropical Medicine have conducted important animal experiments on this subject. They find that the bihydrochlorides of quinine, quinidine, cinchonidine and cinchonine when injected in the usual strengths into the muscles of rabbits caused oedema, irritation and necrosis of the tissues. Contrary to the usual belief, there was little difference in the action of cinchonine as compared with quinine. They go so far as to say that the injection of these alkaloidal salts into the muscles of man should be considered as malpraxis, and that "there is only one method of administering the cinchona alkaloids and that is by the mouth."

"Very rarely in grave cases quinine base should be injected intravenously."

Without going quite so far as the authors in their condemnation of intramuscular injections of quinine and

cinchonine, we are of opinion that this method should be reserved for cases in which there are good and sufficient reasons, such as persistent vomiting or failure to absorb the drugs. The proportion of cases in which serious consequences follow in practice from intramuscular injections is small, but is large enough to justify us in reserving the method for those cases in which there is a real necessity for the procedure.

The Nature of Diabetes Mellitus.

Jl. Amer. Med. Assocn., Vol. 83, 1924, p. 1423.

AN important paper by Dr. Cammidge of London raises the question of the real nature of diabetes mellitus. The prevailing view appears to be that the disease arises from pancreatitis and that any form of glycosuria which arises from non-pancreatic causes is not true diabetes.

We are faced with the old problem of giving an accurate scientific definition to a name which was used in a loose and unscientific manner for generations, and it is evident that the time has not yet arrived when it is possible to give a final definition of the term diabetes. We must continue to regard diabetes as a symptom, and the only scientific procedure which is permissible at the moment is to define the conditions of which it is a symptom.

The discovery of insulin has been regarded as evidence of the unity of diabetes, because all forms of glycosuria yield to the drug. Cammidge argues that any form of glycosuria produced experimentally will yield to insulin even if the pancreas be intact.

It is not possible to follow Cammidge in detail through his masterly exposition of the subject, but he states that his clinical experience goes to show that about 38 per cent. of his cases offer evidence of pancreatic deficiency of an absolute degree, 32 per cent. have relative deficiency associated with excessive glyco-genesis, while the remainder showed no evidence of pancreatic defect. Cammidge adds that if only severe progressive cases are taken into account, no less than 80 per cent. of them show absolute pancreatic defect.

It would be interesting to investigate diabetes in India from this point of view to see whether the same proportion of the cases falls under these three heads. Clinicians here are inclined to agree that there are two main forms of the disease, one with primary disease of the pancreas, in which the disease runs a rapid course, the other a slow and insidious form occurring in persons who have been guilty of years of physiological unrighteousness, who have eaten carbohydrates to excess and taken too little exercise. In this form it is believed that the glycogenic function of the liver and the activity of the internal secreting cells of the pancreas have been overstrained for a long time; the pancreas is more sinned against than sinning and it breaks down through over work. Eventually the pancreas becomes diseased but only as a secondary measure. Probably there is over production and defective utilisation of sugar. Here is a case in which international co-operation between research workers might lead to valuable results. It is obvious that the prevention and cure of the two distinct forms of diabetes must be worked on quite distinct lines, and a slavish following of the teaching of western scientists may result in erroneous views as to the control of the disease. Cammidge's paper is of exceptional interest to us in India, and it is to be hoped that the lines of thought suggested by him will be worked out here as well as in western countries.

Urea Stibamine.

MAJOR H. E. SHORTT, I.M.S., and DR. U. N. BRAHMACHARI have papers on this drug in the October number of the *Indian Journal of Medical Research*. They continue to have remarkably good results, and Major Shortt presents a series of 20 consecutive cases all of which

were claimed to be cured. The standard of cure appears to be microscopical and cultural examinations on the completion of treatment. This result is certainly wonderfully good and it is to be hoped that it will be possible to ascertain the permanence of the cures by following up the patients for a further period of at least six months.

Dr. Brahmachari records a series of eleven cases, all cured by courses of injections lasting from ten to fourteen days. Negative blood cultures at the end of the treatment are accepted as evidence of cure, but here again it is necessary to follow up the cases as it seems to be quite possible that a negative blood culture immediately after the course of treatment may not indicate complete and final sterilization. If so short a course of treatment should be found to be followed by a permanent cure in all cases, the treatment of kala-azar will be reduced to the utmost simplicity.

Urea stibamine has now been tested very thoroughly as far as its immediate effect on the disease is concerned, especially in the early stages. We hope it is not hypercritical to ask for the after results as these are of the utmost importance. Other lines of treatment are held by some to bring about similarly good results, but relapses are reported to be not uncommon. Dr. Brahmachari's next step will doubtless be to publish in detail the process of manufacture of urea stibamine, so that it may be made available for general use at a reasonable price.

Studies in Dracontiasis.

DR. HAMILTON FAIRLEY in the October number of the *Indian Journal of Medical Research* gives a most valuable analysis of 140 cases of dracontiasis. The disease is most prevalent in western Madras and in the Deccan, where nearly 3 per cent. of the population are affected.

Deaths are few, but incapacitation is great; in one village nearly 25 per cent. of the population were off work for about a month every year owing to the disease.

The incubation period is probably about a year. The chief incidence in Bombay is from March to June. Multiple infestations and repeated infestation are common. Some people appear to be resistant owing to the condition of their gastric juices.

The onset is with urticaria, gastro-intestinal disturbances, fainting, giddiness and dyspnoea. These symptoms are followed within a few hours by local signs of the worm in the subcutaneous tissues. These signs are (1) local itching in 81.5 per cent. of cases. (2) A small vesicle which is often ruptured by scratching. (3) A spreading oedema of the part. Sometimes the first indication of the disease is the appearance of a palpable worm (10.8 per cent.).

Urticaria of a general type occurs in about 40 per cent. of the cases. There is often swelling of the eyelids and infection of the conjunctive. The urticaria lasts for less than $\frac{1}{2}$ to 12 hours in most cases. Half of the patients who have urticaria also have nausea or vomiting. Fever occurs in about 15 per cent. of the cases.

Severe dyspnoea is sometimes seen due to the bronchial oedema. The general symptoms which so often precede the appearance of the worm are believed to be due to some toxic materials exuded by the female worm in the tissues.

Local Lesion.—The blister is from 2 mm. to 7 mm., its contents are clear sterile serum containing leucocytes and embryos of the worm. Aspiration under aseptic conditions is advisable for diagnosis and treatment. The ulcer which follows the rupture of the blister has a central whitish necrotic zone in pink granulation tissue covered with a gelatinous exudate.

The situation of the local lesion was the lower extremities in 86.5 per cent. of the cases, in the others it was the arm, trunk, buttock and scrotum. Secondary bacterial infection occurs with staphylococci, streptococci or colon bacilli. These are usually introduced by

retraction of the stretched worm when it is broken in attempts at mechanical extraction. Acute abscesses are common, cellulitis and buboes may occur. Septic arthritis followed by ankylosis may lead to deformity; calcified worms may persist for years when the worm dies under aseptic conditions. The blood picture is characterized by eosinophilia (about 15 per cent., rarely up to 63 per cent.). With bacterial infection there is naturally a leucocytosis. Tartar emetic was regarded as a failure. The essential point in the treatment of septic cases is mechanical traction of the parasite.

Liver Abscess.

In the *Lancet* of November 15th, 1924, Lieut.-Colonel E. O. Thurston, I.M.S., records his further experience in the treatment of liver abscess. His original publication in the *Indian Medical Gazette* in 1914 did much to make aspiration the operation of choice in India, but evidently other countries have lagged behind and are still content with the barbarous open operation.

The adoption of aspiration in India was due to Sir Leonard Rogers, who pointed out that emetine is capable of controlling the active infection by the amoebæ, and that apart from this there is just as great an objection to opening an aseptic liver abscess as there is to opening a pyoæ abscess or any other collection of pus which is not infected with septic organisms. To place such abscesses in open communication with the outside air has always been found to be most dangerous, and we have definitely departed from the surgical fetish which insisted that "where there is pus there ought to be an incision." The teaching now is "where there is aseptic pus there should not be an incision unless there is some urgent need or overwhelming indication for it."

Thurston was one of the first surgeons to adopt this rule in dealing with liver abscess, and his results show a series of 64 cases of liver abscess treated on these lines with a mortality of 14 per cent. These figures form the best possible justification of the correctness of the line of treatment which was adopted. Of the cases, 49 were treated by aspiration alone, there were nine deaths among these. Nine cases were treated by incision, cleaning out the cavity with gauze and sewing up the wound in layers. Some of these broke down, but healing was much more rapid than with the open operation, others healed up soundly without complications, all of these recovered. In two cases incision and drainage were necessary, both of these recovered. Repeated aspirations were needed in some cases. In one case nearly 100 ozs. of pus was removed at one aspiration. In two cases drainage after aspiration had to be adopted.

To estimate the results it must be added that all the cases were very advanced or very acute and there was no selection of cases. Most of the fatal cases were of a particularly unfavourable type, two were moribund, two had multiple abscesses, one was a very old man with albuminuria and glycosuria, in fact it is stated that in uncomplicated cases there were no deaths. Thurston regards adequate emetine treatment as an essential part of the operation and in the later cases his practice was to give two grains of emetine hypodermically while aspiration is going on. The injection of quinine or emetine into the cavity has not been found useful. In uncomplicated cases the stay in hospital was a week or ten days during which about six grains of emetine were given.

The economy in time and dressings is an important factor, but the most essential point is the obviation of risk of septic infection. A Potain's aspirator is used, local anaesthesia is preferable, especially in severe cases. The site of puncture is towards the upper part of the abscess, especially in epigastric cases. In abscesses extending down to the umbilicus the point of entry of the needle is from above downwards just below the costal margin because of the rapid upward retraction of the liver which takes place during the operation. When the abscess points, entry

through healthy skin is made when possible to prevent leakage. The wound is closed with collodion on cotton wool. Two bottles are kept ready so that when one is filled the other can be used at once. When the flow shows signs of weakening, an assistant uses the exhaust syringe without closing the stop cock on the tube attached to the cannula. If the flow is checked by debris the trocar or a stylet is inserted.

The cavity is emptied as completely as possible and the wall of the abscess is searched with the cannula, in this way pockets are sometimes found. The puncture is stitched with one horse hair and the wound dressed with collodion on cotton wool.

Four cases were aspirated and subsequently drained, either because the abscess was obviously septic or because aspiration was unsatisfactory. Only two cases were incised at once, one was a doubtful swelling which had to be explored, another was septic.

In cases with a doubtful swelling in the epigastrium open operation with cleaning of the cavity with gauze and primary suture is regarded as the safest procedure. There were nine of such cases, seven of which healed by first intention.

Two of these cases broke down later, but the results were better than with drainage. Finally it appears that the only indication for drainage is sepsis. It is important to emphasise the correct treatment of liver abscess, for though most workers in India are familiar with this, workers in the other parts of the world and some new comers to India are not aware of the dangers of open operation, which in such a series would probably have yielded a mortality of 60 per cent owing to septic complications which cannot be prevented even with the most elaborate precautions.

Thurston's cases were treated in an Indian hospital in which the patients were anxious to go home at the earliest possible moment; otherwise a longer course of after-treatment would doubtless have been carried out as a single course of emetine cannot be regarded as a cure of the underlying amoebiasis. It seems likely that early cases which are not of a fulminating nature and which are not complicated with some other serious illness are almost invariably cured.

It is obvious that a record like this is of the greatest value, owing to the absence of selection in the cases. Colonel Thurston is to be congratulated on having obtained remarkable results by methods which are capable of being practised by any surgeon even under the unfavourable conditions which prevail in most Indian hospitals.

The Treatment of Empyema.

By W. H. C. ROMANIS.

Practitioner, November, 1924.

THE operation varies with the nature of the organism. When the pneumococcus is found drainage can sometimes be dispensed with, if primary closure fails, no harm is done and drainage can be resorted to. If other septic organisms are present drainage is essential and resection of a rib is necessary except (1) in the case of patients who are desperately ill; (2) in children in whom suction or syphon drainage is desirable. A general anaesthetic is desirable, either gas and oxygen or ether being preferable. The chest should be opened as low as possible, usually between the mid-axillary and scapular lines by removing the eighth or ninth rib. The vertical skin incision is best. A wide short tube is used, this should not touch the diaphragm or lung. The tube should not be left in for more than four or five days and may be removed when the discharge becomes thin and serous. Lung expansion is encouraged from the beginning by blowing exercises like blowing up air cushions. Exploratory puncture with examination of the fluid to determine the organism present is an essential preliminary step and in many cases it is justifiable to wait for 24 hours to allow of a cultural diagnosis before operation.

Early Subacute Cholecystites.

By Dr. WILLIAM BAIN.

Practitioner, November, 1924.

THE disease may occur in the absence of gall-stones and often yields to treatment. It is five times more common in women than in men and usually in women who have borne children. It is suggested that gall-stones may often be formed in the absence of sepsis, and that the sepsis which occurs in many of the cases is secondary to the formation of the gall-stones.

The symptoms are often those of epigastric discomfort and flatulent indigestion. The characteristic sign is tenderness on deep pressure in the gall-bladder region, this is elicited by making the patient bend forward and breathe deeply. Sometimes duodenal ulcer is difficult to distinguish, but gastric analysis may help. In ulcer there is usually hyperchlorhydria, in cholecystitis hypochlorhydria. X-ray examination with a bismuth meal often helps. In treatment it is important to seek for a septic focus and attend to it if present; the teeth and tonsils should be carefully examined. A simple diet from which eggs, animal fats and pastry are excluded is adopted.

The bowels must be kept active by an aperient like aloes or phenolphthalein before dinner and a morning saline. Urotropin is often of value. Moderate exercise is desirable. Early cases usually do well and in most cases operation is not needed.

Cataract, the Expression Operation.

British Medical Journal, October '11, 1924, p. 662.

At a meeting of the British Medical Association Lieut.-Colonel Henry Smith, I.M.S., in the discussion on intracapsular extraction of cataract drew attention briefly to certain issues on the importance of which enough stress was not laid.

Control of the Eyelids.—Thorough control of the orbicularis, whether by novocain or by mechanical means, or by both when novocain failed, as it not infrequently did, was absolutely essential if the operator was to have a fair chance.

The Incision.—For an intracapsular operation the incision should be of 180 degrees, commencing in or just behind the sclero-cornea. If accidents turned it into a capsulotomy operation no harm was done: one never regretted having room enough, but always regretted having too little. Bursting of the capsule in expression was almost always due to too small a wound, and was generally due to the same cause in the traction form of extraction.

The Stanculeanu, Kalt, Knapp, and Sinclair methods were substantially the same. They would, he considered, be all improved if the operator made traction with one hand and pressed a squint hook on the flat—the point directed upwards—on the lower third of the cornea to assist in dislocating the lens. Dr. Barraquer's method would, he thought, be improved by using the squint hook in the same way. This would also render the capsule less liable to tear in all these cases. Dr. Barraquer still laid stress on not tearing the suspensory ligament some distance from the lens: to do so would undoubtedly imply more force than was justifiable. Having repeatedly examined lenses for this very thing with a magnifying lens before Dr. Barraquer commenced intracapsular extraction, he had never once found tags of suspensory ligament attached to the lens. He did not think that the zonule was ever thus torn, whatever method was adopted. The detachment was always directly from the lens, so that they need have no fear on this issue; vibratory movement had nothing whatever to do with it. There seemed to be a general demand for a less complicated instrument than Dr. Barraquer's, and Messrs. Down Brothers were likely to supply it in the near future.

The Physical Condition of the Lens.—Too much stress was laid on this issue. From the practical point of view

it was either a hard cataract or a Morgagnian cataract; if the former the plane of the iris was pushed forward, if Morgagnian it was the most ideal for the capsulotomy operation, or for the procedure which he had long advocated—the least favourable for any of the other methods of intracapsular extraction. The idea that the younger man must investigate every cataract and draw inferences bearing on operation by the newest methods of examining the lens rather tended to frighten him unnecessarily. The younger men in later years would surely come to agree with him that they were taught a thousand-and-one terrors, which proved to be bogies designed apparently to make sure that they would never draw blood and never acquire enough confidence to operate.

Escape of Vitreous.—People talked as though escape were not incidental to the old operation. Professor Parker of Detroit read a paper at the annual meeting of the American Medical Association in 1921, giving about 14 per cent. in his experience of about 1,400. It was much more serious in the old operation on account of the lens matter and capsule left behind than in the intracapsular operation. A large escape was as fatal as a choroidal hemorrhage: a small escape was of no consequence. Nature was unable to repair the large one, but was able to repair the small one; this was the only explanation why eyes with a small escape wore as well as those with no escape.

People seemed to swallow the conclusion that pressure and friction must do harm; therefore it did do harm; they drew a conclusion from one premise instead of two, and advanced no facts. The epithelial surface of the cornea would stand a surprising amount of friction without showing signs of reaction, and considerable pressure and pressure-strain was well tolerated and need not be feared, always provided reasonable skill was used. He had frequently extracted in the capsule down to 30 years of age, and a few times down to 25 without any sinister result. No one operating on patients over 50 years of age would have to use half this amount of pressure-strain.

Reference had been made to Dr. Barraquer's cases in America. Lieut.-Colonel Smith had had a similar experience. There was no finer body of sportsmen in the world than American surgeons, but in every country there were a few who "shoot the pigeon sitting." Dr. Barraquer operated on some cases and never saw them again; some of them were talked over or reported on adversely, the venom losing nothing as it passed round. The speaker was similarly treated at Chicago, but on independent inquiry it was found that the results were twice as good as reported; 6/50 turning out to be 6/6, and so on.

They were told that the old operation was satisfactory; why then this search for a better one? Their answer was: Take the immature cataract as one of the many cases in which it was not satisfactory. In this and every country they were very numerous; men in the prime of life—50 to 60—found themselves put on the shelf, so to speak, for five years, ten years, or even for life, until their cataracts were ready for the old operation. The penalty of waiting was tremendous; the demand was insistent, and they must give such patients relief. The old operation could not do it, but the new one could. India with its 40,000 cataracts a year, mostly intracapsular, would determine this question.

The Horizontal Position as a Cause of Puerperal Sepsis.

In the *British Medical Journal* of September 27th 1924, p. 557, Dr. Henry Corby of Cork makes the interesting suggestion that prolonged rest in the horizontal position after labour results in the lodgement of lochia in the uterus and vagina and so promotes sepsis.

He finds that the poor women who are treated as extern patients are much less liable to sepsis than hospital patients, and he attributes their freedom from sepsis to their habit of getting up within three to five days after labour.

He brings forward other evidence which points in the same direction and argues that the free discharge of the lochia is Nature's method of getting rid of debris and other pabulum for septic organisms. He now advocates early sitting up in bed at stated intervals soon after the completion of labour and he believes that the results are good.

Pruritus Ani.

DR. LOUIS SAVATARD of Manchester writes a special article in the *Lancet* of November 1st, 1924 on the treatment of pruritus ani.

He regards local causes as being even more important than general, and he instances catarrh of the rectum, threadworms, piles, polypi, fistulae, fissures, warts, etc., each of which conditions calls for appropriate treatment. Want of cleanliness after defaecation is also important and the use of moist pledgets of cotton wool followed by a dusting powder is recommended.

A thorough examination of the parts is essential before treatment is started.

After cure of the local lesions the itching may persist, in these cases various local remedies may be of value.

Such are:—

- (1) Carbolic lotion, 1 in 80.
- (2) Carbolic oil, 1 in 20.
- (3) Hydrarg. Ammon. grs. xv. ad. oz. i. of benzoated lard.
- (4) Calomel powder rubbed on the part after cleaning and drying.
- (5) For cases with thickening of the skin salicylic acid 6 per cent. in 50 per cent. alcohol, used as a paint.
- (6) X-rays are of the utmost value if employed by an expert radio-therapist. Four unfiltered doses of half pastille each at fortnightly intervals and then two further exposures after a month's rest are advised.
- (7) Zinc ionization is recommended by McLeod.
- (8) Vaccines of *Streptococcus faecalis* as used by Dr. Murray of Syracuse are worth trial in obstinate cases.

Uncalled for Appendicectomy.

DR. BETTMANN of Chicago deals with this important subject in the *Journal of the American Medical Association* of October 18th, 1924.

O'Neil of Massachusetts reports that 25 per cent. of the patients who had urethral calculi had previously been operated on for supposed appendicitis.

"Chronic appendicitis" is still the opprobrium of surgery, a large proportion of patients operated on for supposed appendicular trouble are not relieved.

Sonnenburg states that after 40 very few people have a normal appendix, yet many of these have never suffered from appendicular trouble, hence the removal of a diseased appendix does not necessarily mean the removal of the cause of abdominal disease.

It is not easy to determine whether symptoms are really due to the appendix in chronic cases, though true relapsing appendicitis is easy of diagnosis. Definite acute attacks occur in such cases and operation is nearly always followed by relief. Relapsing appendicitis should therefore be distinguished from "chronic appendicitis." In the latter condition not more than 60 per cent. of the clinical diagnoses are justified.

Stanton insists that in true cases there are almost always attacks of dyspepsia with epigastric pain radiating to the neighbourhood of the umbilicus or to the lower abdomen.

Nausea or vomiting associated with the pain occurs in nearly every case. Mere pain in the right lower quadrant apart from nausea is seldom relieved by appendicectomy.

Bettmann analyses 170 cases of failure to relieve by appendicectomy and finds that:—

66 were due to inadequate study of the case.

20 were due to the existence of peptic ulcers.

16 were due to the disease of the gall-bladder.

10 were due to misleading x-ray reports.

9 were due to genito-urinary cases.

12 were due to cases of colitis.

9 were due to pulmonary tuberculosis.

20 were due to miscellaneous causes like gastritis, hernia, ovarian disturbances, etc.

Mere pain and tenderness over McBurney's point is not enough to justify the diagnosis of chronic appendicitis. Prolonged observation of doubtful cases is essential, as an exploratory operation is by no means always a harmless procedure and a considerable number of persons have been damaged for life by such operations.

The Electrical Stethoscope.

DR. GAMBLE of Philadelphia has written an interesting account of this instrument in the *Journal of the American Medical Association* of October 18th, 1924. It is possible to convey heart sounds in a satisfactory manner to large audiences, as was demonstrated at the last annual meeting of the American Medical Association when cardiac sounds, râles, and even foetal heart sounds were heard by 528 medical men seated in one hall.

With recent modifications even better results have been obtained, and the sounds can be recorded on a phonograph record so that they can be reproduced when desired. By the use of electric filters certain sounds can be selected and others damped out so that certain murmurs can be detected which cannot be heard by ordinary methods. We are evidently on the eve of a revolution in the methods of teaching the recognition of abnormal sounds produced in the chest and other parts of the body.

The "Journal of Ayurveda."

WE welcome the appearance of a journal whose objects are "to bridge over the gulf that seems to be between Ayurveda and Western Medicine" and "to open up to the inquisitive world the treasures of the science and art of Ayurveda for the advancement of science and the relief of suffering humanity."

Ayurvedic medicine has been so much in the public eye of late that everybody is anxious to know more about it, and we trust that our ignorance will be dissipated by the *Journal of Ayurveda*. The editor has done us the honour to quote extensively from a recent editorial in the *Gazette* (Fashions in Medicine), and it is evident that he has taken seriously to heart an article which was written in lighter vein and was intended to be read in the same manner. In a recent number of the *Journal* we regret to notice that the writer of "News and Notes" has descended to the use of objectionable personalities.

These are not likely to benefit the cause of Ayurveda nor to hasten the day when all of us will practice really scientific medicine.

The aims and objects of the *Journal of Ayurveda* are the same as ours, although we are travelling on different roads, our sincere desire is that we may come together without undue delay, and when we do meet, may we both be found to be honest seekers for the truth.

Reviews.

LORD LISTER.—By Sir Rickman John Godlee, Bt., K.C.V.O., M.S., F.R.C.S. 3rd edition, 1924. Oxford: The Clarendon Press. Pp. 686. Illustrations 34. Price 21s. net.

THE medical man who wishes to gain a clear idea of the broad foundations upon which modern medicine and surgery are based should read two great books which are almost twin classics; René Valléry Radot's "Life of Pasteur" (English translation by Mrs. Devonshire), and Sir Rickman Godlee's "Lord Lister," the re-appearance of which in a third edition we cordially welcome. Both are finely written studies of immortal subjects, and deal with that splendid period of medical history when the work of the great pioneers was clearing the ground of the jungle of empiricism and tradition, and erecting the pillars of rationalism and experimental enquiry of the present-day "temple of medicine."

Head and shoulders above them all in Great Britain rose the figure of the greatest and noblest of British surgeons, Joseph Lister (1827-1912). Something of his nobility of spirit and glamour of personality may be gathered from a quotation from his graduation address to students in 1876; "If we had nothing but pecuniary rewards and worldly honours to look to, our profession would not be one to be desired. But in its practice you will find it to be attended with peculiar privileges; second to none in intense interest and pure pleasures. It is our proud office to tend the fleshly tabernacle of the immortal spirit, and our path, if rightly followed, will be guided by unfettered truth and love unfeigned. In the pursuit of this noble and holy calling I wish you all God-speed."

In these pages Sir Rickman Godlee writes in an eminently readable and charming style of that wonderful career of 85 years, whilst the finely executed portraits with which the volume abounds give an added interest to the volume. Lister was the son of a very remarkable man, Joseph Jackson Lister, a Quaker, a vintner, a Fellow of the Royal Society, and one who did much to bring microscopes and optical apparatus to their present day condition of perfection. Wisely, Sir Rickman Godlee allows Lister to tell much of his own story in abstracts from his long letters to the father to whom he was so devoted. It was customary in Lister's day for predatory Scotch surgeons to qualify in the North and then to seek livelihood and fame in the more genial and more wealthy atmosphere of the Southern kingdom. Lister reversed this procedure; he qualified from University College Hospital, took the F.R.C.S. (England) in 1852, and went to Edinburgh. Here he became house surgeon to that remarkable surgeon and wonderful teacher, James Syme, who welcomed such a recruit with open arms. Syme's consulting rooms were in the city, but he had a charming house at Millbank, once a pleasant suburb of Edinburgh, but to-day swamped in the midst of its slums,—a house which was the meeting place of a distinguished band of Edinburgh surgeons and intellectuals and foreign and learned distinguished visitors. From the very commencement Syme's influence and his system of clinical teaching exercised the greatest influence upon the career of Lister. Lister was exceedingly well qualified, as far as London standards then went; in Edinburgh, however, he found established a school of surgery which was far in advance of London standards, and in Sir Rickman Godlee's pages we have here presented an interesting account of that celebrated Edinburgh school; also indeed of the very acrimonious controversies which abounded between the chief protagonists of the day, "Edinburgh, Syme, super-house-surgeon," wrote Sir George Buchanan, his fellow student, from Univer-

sity College Hospital to Lister in 1853, "Why, you must be in a perpetual state of bliss of the most aggravated description, operations being to you a foretaste of the joys prepared for the good. We saw your name in the papers as an adopted child of Syme's, reporting a case for him." It was a not inaccurate description of the relationship between the two.

Having married Syme's daughter, Agnes, and after a continental tour, Lister settled in Rutland Street in Edinburgh in 1856, and at once devoted himself to the remarkable series of studies on the pathology of inflammation which preceded those of Metchnikoff, chiefly dealing with the vascular changes associated with this process. In the same year, he commenced to lecture to students, his first class consisting of 23 pupils. His lectures were entirely different in two ways from those of his contemporaries; he taught far more pathology than surgery, and in place of academic lectures, had patients brought into the lecture theatre one by one as was also Syme's custom. "He impressed us all deeply from the beginning...he worked us very hard...he taught us pathology more than surgery. The general impression was that he was a great thinker, and he was treated as such by all the men," wrote Sir John Batty Tuke, one of Lister's pupils, in later years.

The experiments on inflammation were succeeded by a study of the conditions of blood coagulation and of "spontaneous gangrene." By this time he was known as a young surgeon of great promise, and a keen pupil of Syme's and in 1860 the chair of surgery at Glasgow University was offered to him and he accepted it, to be followed in 1861 by appointment as surgeon to the Royal Infirmary. Here he contributed articles on amputations and anaesthetics to Holme's *System of Surgery*, and contributed many technical papers on new technique and instruments to the medical journals. All the time, however, his chief interest was in his laboratory and to him surgery rested upon the wide basis of pathological study.

The conditions of surgery in that day, however, are now almost inconceivable. "Any attempt to realise what teachers taught and students learned, and, in fact, what all doctors thought about hospital diseases in 1865, is like trying to appreciate the state of mind of the inhabitants of this planet before they had begun to doubt that it was the centre of the universe," writes Sir Rickman Godlee. "Hospitalism was rampant... and the surgical wards were dominated by erysipelas, septicæmia, and gangrene. When a surgeon operated in those days, what he hoped to obtain was an open wound streaming with 'laudable pus'." The mortality rates after amputation of limbs were 43 per cent. at Edinburgh Infirmary, 39 per cent. at Glasgow Infirmary, and some 75 to 90 per cent. in military practice; Syme indeed had given it as his reasoned conclusion that in all compound fractures of the lower limb, immediate amputation ought to be resorted to, and no attempt be made to save the limb. The mortality among women in child-birth from puerperal sepsis was something like 1 in 7, and every lying-in hospital in the land was a horrible focus of dirt and death. In many hospitals surgical or maternity wards had had to be closed on account of sepsis. Surgeons operated in filthy frock coats encrusted with an accumulation of years of blood, pus and dirt; their assistants attempted to secure equally filthy coats, whilst the ligatures for operation were carried, as badges of honour, in the buttonhole of the lapel of the coat. Sepsis reigned supreme; "I have come to the conclusion," wrote Cadge of Norwich, a well known surgeon, "that pyæmia, if it does not find its birth-place, does find its natural home and resting-place in hospitals; if and although a hospital may not be the mother of pyæmia, it is its nurse." Erichsen, a distinguished surgeon of the day, had just written a book in which he claimed that surgery had reached finality; it was too dangerous to open the abdominal or other body cavity, and all that remained in the way of future progress was to improve the technique of the

then-existent operations upon the limbs. Leibig, the German chemist, taught that suppuration in a wound was due to the access to it of the oxygen of the air; this could not possibly be excluded, and hence matters could not be improved. All sorts of measures were tried; giving a greatly increased space to the beds in the surgical wards, immersing operated-upon limbs in continuous water baths, testing different drugs and remedies in solution in dressings; nothing succeeded. Conditions were such as to appal Lister and every other thinking surgeon of the day. Lister was busy with a study of the exact position of the abdominal aorta and the details of excision of the wrist, but his thoughts were continuously upon the subject of inflammation and suppuration, his laboratory hours continuously spent upon devices to combat sepsis.

Meantime, however, upon the continent matters moved—as if in accordance almost with some great fore-ordained plan—to their appointed end. Semmelweis in Vienna made the remarkable observation that, in a large lying-in hospital, the chief mortality from puerperal fever occurred when the attendant physicians went from the post-mortem room to the lying-in wards, and that septicæmia and puerperal fever were identical diseases; also that the mortality was lower in the wards where the attendants were all females, who did not attend the post-mortem room, and highest in the wards where students attended who had visited the post-mortem room. He was ridiculed, persecuted, and deprived of his appointment; he died in a lunatic asylum; but to-day his memory is honoured throughout Europe.

In France, Louis Pasteur had been steadily at work. The fermentation of beers, taught Leibig, is due to the presence within them of *dead* yeasts; the yeasts, upon dying, liberate a catalytic agent which causes the fermentation. Fermentation, upon the other hand, taught Pasteur, is not due to *dead* yeasts at all, but to living and multiplying yeasts, which require sugar for their nutrition, and in the course of their metabolism produce alcohol from it. It was the first echo of a controversy which convulsed Europe for years; in France the battle being between Pasteur and Pouchet, in England between Tyndall and Bastian. Life, taught Pasteur, comes only from pre-existing life; "*le germe c'est la vie, et la vie c'est le germe.*" Sepsis in wounds, he claimed, is due to germs from the air or from the dirty hands of the surgeon or his assistants being introduced into them; and he proceeded to further matters by his discoveries of the staphylococcus and the streptococcus.

At that time "antiseptics" were already recognised, but the word then meant something far different from what we mean by it to-day; in those days an "antiseptic" was some drug or other which might help to reduce already pre-existing sepsis; to-day we use it for a drug which will prevent sepsis from occurring. Lister had for some years been carefully feeling his way to the introduction of antiseptics in surgical practice, but Pasteur's published views at once gave him the necessary clue. If Pasteur was right, if suppuration was due to germs from outside being introduced into an otherwise surgically clean wound, matters were simplified. Some substance must be used which would kill all such germs and prevent their access to the wound made during and after the operation.

The antiseptic principle introduced by Lister was something quite new. It was *not* the attempt to overcome sepsis which had already been established, as some of his contemporaries misrepresented the case; nor did it consist in the introduction of carbolic acid lotions in surgical practice. It was a new method, a new visualisation, a new procedure, based upon experimental pathology. Several surgeons prior to Lister had used carbolic acid, Lemaire had investigated its value as an "antiseptic," and it was in use,—in the crude form of that day,—as a deodorant for the treatment of the sewage of Carlisle. Lister introduced it into his surgical practice and experimented upon it in his laboratory. At first he used the crude acid, swabbing the

wound out with it after operation, and covering it with a small dressing of lint soaked in the crude acid and covered with a sheet of tin or lead foil in order to keep the volatile acid in contact with the wound. The result was to produce a sterile scab, under which the wound healed aseptically.

He soon realised, however, that the crude undiluted acid was unsuitable, and commenced to use lotions of 1 in 20 and 1 in 40 strength; strengths which we to-day recognise as still irritant to the tissues. In 1867 he published the first of his famous papers upon the antiseptic principle, giving the wonderful results obtained in his first series of 11 cases of compound fracture treated with carbolic acid. Also he now introduced a second principle into surgery; previously it had been customary to leave the ends of ligatures long, so that they hung out of the angle of the wound, and were removed as they sloughed off. Confident in his antiseptic technique, Lister began to cut the ligatures short and to leave them buried *in situ*. It was a second new principle in surgery, of importance only secondary to the introduction of the antiseptic principle.

Subsequent to the introduction of the antiseptic principle, the evolution of modern surgery was both rapid and brilliant. Lister introduced the carbolic spray,—at first in the form of the hand spray, later of the mechanically worked "donkey engine," still later the steam spray. Under these sprays the atmosphere around the operation wound was saturated with the vapour from a 1 in 20 solution of carbolic acid in the hope of killing germs which might have access to the wound. Also he was continuously at work trying to improve the dressings of the wound, the principle being to apply a first dressing which should contain carbolic acid, then to cover this with a "protective" impermeable dressing such as oiled silk which should prevent loss of the antiseptic by volatilisation; and the cerate dressing, the putty dressing, carbolised gauze, and finally the double cyanide gauze which is to-day in such frequent use, followed.

Lister's struggle, however, to establish the new principle was a long and bitter one. Gradually there grew up a younger generation of surgeons, many of them his own pupils, who spread abroad and who themselves practised the new doctrine. Thus at Edinburgh progress was rapid, whilst several of the staff at Glasgow became converts to his ideas. In Germany especially was antiseptic surgery taken up with enthusiasm. In France, however, progress was far slower, and the sufferings of the French wounded during the Franco-Prussian war of 1870 under the old régime of sepsis and filth were indescribable. In London "listerism" was generally sneered at. Many of the older surgeons, especially Sir James Simpson, Lawson Tait in Birmingham, Nunneley, and Savory, attacked Lister. His ideas and views were entirely misrepresented; he was accused of trying to lay claim to be the first surgeon to use carbolic acid, his methods were "tested" in a half-hearted method with bad results; that what Lister had done was to introduce a new idea and a new principle was grasped by none of his critics; to-day the echoes of that fierce controversy sound almost incredible. For example, Lawson Tait sneered at antiseptic surgery to the day of his death; yet in his own practice Tait used a technique which was an approximation to the aseptic method, repeatedly washing his hands and pouring gallons of warm boiled water into the peritoneal cavity with which to flush it. Yet, despite a fierce and almost unanimous opposition from the older school, antiseptic surgery gradually became more and more universally practised—on account of its excellent results.

Lister had created antiseptic surgery; his use of the short ligature had revolutionised surgical practice; yet a third great problem faced him; that of the best method of arresting hæmorrhage in aseptic wounds. From 1867 he was continuously at work investigating the best methods of preparing and sterilising catgut, work which led to the modern chromicised ligature.

The introduction of an absorbable ligature, in place of the old-fashioned thread one, again almost revolutionised surgical practice. Again he was misrepresented; what he claimed was that the catgut was invaded and subsequently replaced by fibrous tissue; what his opponents said he claimed was that the catgut was absorbed by the body fluids. In chapters 16 to 22, Sir Rickman Godlee gives a vivid and very interesting account of the fierce controversies out of which the antiseptic method arose, to be finally almost reintroduced into England from Germany in improved form.

In 1869 he was appointed professor of clinical surgery in Edinburgh; in 1869 his father died, and in 1870 his great friend Syme. By degrees the work in his laboratory became more and more bacteriological, experiments to confirm Pasteur's views on the germ theory, and a study of lactic acid fermentation. This brought him into correspondence with the great French genius; and led to a medical *entente cordiale*, which it is pleasant and refreshing to look back upon in these later days when the two great nations have stood shoulder to shoulder through war and suffering, and have learned to appreciate each other better. One of the chief exponents of the germ theory in Great Britain was the great physicist Tyndall, whose optical studies upon the dust of the atmosphere and whose popular lectures to lay audiences did much to familiarise the populace at large with the germ theory.

A still further improvement in surgical technique introduced by Lister in 1871 was the introduction of rubber drainage tubes. Previously, when ligatures had been left long and hanging out of the angle of the wound, it was thought that these might improve drainage. Actually they became blocked with clot and provided no drainage at all. The story has often been told of how Lister, when operating for axillary abscess upon Queen Victoria herself, during a stay at Balmoral, took a bit of rubber tubing from the spray apparatus used to produce local anaesthesia, and used it as a drainage tube.

Whilst it was chiefly in the provinces in Great Britain that the antiseptic system spread, in Germany it took deep root. Volkmann was a doughty champion; Stromeyer playfully summarised the situation in the following lines to Lister:—

"Mankind looks grateful now on thee
For what thou didst in surgery.
And Death must often go amiss,
By smelling antiseptic bliss."

The Munich hospital was notorious for its terrible condition of "hospitalism," hospital gangrene occurring in no less than 80 per cent. of all wounds, whether of natural origin or inflicted by the surgeon. The introduction of Lister's methods abolished sepsis from the institution. Von Bergman at Würzburg, and von Volkmann, and Billroth of Vienna became enthusiastic disciples of "listerism"; whilst Saxtorph in Copenhagen was one of the first to introduce antiseptic surgery on the continent of Europe. By degrees, with confirmation of its value on the continent, and in America chiefly in the hands of R. F. Weir, the principles of antiseptic surgery became internationalised and established. In 1875 the annual meeting of the British Medical Association was held in Edinburgh, an event which did much to establish "listerism" as the guiding principle of British surgery.

In the same year came the now famous correspondence with Queen Victoria regarding the value of vivisection in experimental medicine; a controversy in which, despite his position as Surgeon in Scotland to Her Majesty, Lister did not flinch from expressing his emphatic views that such experimentation was not only essential but even necessary for the study of diseases, even those of animals themselves. The student of to-day will find in these pages of Sir Rickman Godlee's book valuable and emphatic expression by Lister himself of what he owed to experiments upon animals in the development of modern surgery and medicine. In

1876 he gave the graduation address at Edinburgh, emphasising in a very remarkable address to students the high standards and privileges of the medical profession; and in 1877 he moved to London, on appointment to the chair in clinical surgery at King's College Hospital.

In London, Lister found an almost hostile atmosphere; London indeed was far behind both Scotland and the continent in its acceptance of his views. Also his unpunctuality at appointments and his curious preference for leaving the amount of the fee to his patient to decide were against him in private practice. Yet he opened his campaign with a minimal number of both students and beds, and he taught bacteriology and pathological fundamentals, rather than operative surgery. Addresses to the Pathological Society and to the Harveian Society followed. In 1877 he wired a broken knee-cap by open operation,—a novel procedure. "Now when this poor fellow dies," remarked one of his colleagues, "it is proper that someone should proceed against Lister for malpraxis." But the patient did not die, healing took place by what Lister now termed "the usual aseptic course"; the expected catastrophe was averted.

In 1881 there was held the ever-memorable Seventh International Medical Congress in London; when Volkmann in a brilliant address hailed Lister and the glory of England as being indissolubly bound with the greatest advance that surgery had ever made. Pasteur also paid his tribute to the great surgeon, and by now it could be claimed that "listerism" had triumphed; its opponents were in the background; whilst Lister himself in his final address upon the method and principle summarised his views and the struggle of the past years.

There followed the—supposed—controversy between antiseptic surgery, where by the use of strong antiseptics the attempt is made to kill all germs which may have access to a wound, and aseptic surgery, the attempt to prevent by heat and other physical means the access of any germs at all to the wound. As Sir Rickman Godlee rightly claims, such a controversy is to-day of but barren interest; the one method is but the logical development of the other. In actual fact, indeed, the asepticists use very strong antiseptics, iodine with which to sterilise the skin, bioniodide lotion for the operator's hands, and so forth. He proclaims himself frankly as a follower of the antiseptic rather than the aseptic school. And here—in chapter 27—is much valuable writing of special interest to the reader in India. We cannot but consider that Sir Rickman Godlee is right. The aseptic method is only suitable in large and well equipped institutions. The long chain of subordinates upon which the success of the aseptic method depends is a very vulnerable one. Dressings are sent out in sealed and sterilised packages by manufacturers; catgut comes from Heaven alone knows where; there is an army of theatre sisters, nurses, assistants and subordinates, every one of whom must practise an absolutely aseptic technique if sepsis is to be avoided. In actual practice he doubts whether the aseptic technique gives better results than does the antiseptic one. (For our own part, and as regards the small *mofussil* hospitals in India, with few or no skilled assistants and a minimum of equipment, we have no doubts; antiseptics may be irritating to the tissues, but the full aseptic technique is a counsel of perfection and impossible of attainment.)

Space does not permit our following further Sir Rickman Godlee's fascinating story of this greatest of British surgeons. His baronetcy was conferred upon him in 1883; an honour which was especially noteworthy among the very small number of medical baronets who had been created at that day. In London in general his life was easier and with more leisure in it than in Edinburgh; his hours more given to his laboratory and to his "common-place books", (notebooks and records). In 1887, together with Sir Victor Horsley and many of

the leading medical men of the country, he was appointed a member of the Commission sent to Paris to study Pasteur's anti-rabic methods; a Commission which resulted in the Muzzling Order and the extirpation of rabies from Great Britain; in 1893 the celebrated Lister Institute at Chelsea was opened, in the teeth of opposition from antivivisectionists and of lethargy on the part of government officials, and by public subscription; to be subsequently set upon a sound financial basis by Lord Iveagh's noble endowment of £250,000 in 1900. In 1887 came the historic scene at the Pasteur jubilee at the Sorbonne in Paris, when Pasteur and Lister,—the latter representing the Royal Society of London and that of Edinburgh—were the two honoured guests, a celebration immortalised in the etching by Rixens; whilst in 1895 he became President of the Royal Society, a position only once previously held by a surgeon (Sir Benjamin Brodie, 1858-61).

In 1893 Lady Lister died, his intimate companion, secretary and fellow-worker for 37 years. From that time onwards Lister lived a solitary, secluded and saddened life. The laboratory work, the addresses to learned and scientific societies, and his keen and critical experimental work continued, but he withdrew more and more from social and public life. Honours descended upon him and his 80th birthday in 1907 was celebrated all over the world. In 1912 he died, and—in spite of his personal wishes—was buried in Westminster Abbey, where Sir Thomas Brock's medallion of him is for ever memorable. The anthem at the funeral service was singularly appropriate:—

"When the ear heard him, then it blessed him; and when the eye saw him, it gave witness of him; he delivered the poor that cried, the fatherless, and him that had none to help. Kindness, meekness, and comfort were in his tongue. If there was any virtue, and if there was any praise, he thought on these things. His body is buried in peace, but his name liveth for evermore."

Sir Rickman Godlee's fine and scholarly book is a memorable tribute to an immortal subject. We cannot live again those glorious days of the great past; but in its pages we can catch again somewhat of their glamour, of their nobility, and of the great and heroic figure who created and rendered possible modern surgery,—a knight of modern days, "sans peur et sans reproche."

R. K.

THE DIAGNOSIS AND TREATMENT OF THE INFECTIOUS DISEASES.—By F. H. Thomson, M.B., C.M. (Aberd.), D.P.H. H. K. Lewis & Co., London, 1924. Pp. VIII + 208. Price 7s. 6d. net.

This is a thoroughly practical little book which is based on 34 years experience of infectious diseases in connection with the Metropolitan Asylums Board of London.

The author has had an extensive knowledge of the difficulties which are encountered by the general practitioner and his chief aim has been to deal with those doubtful points which are commonly slurred over in the text books.

There is a good article on lethargic encephalitis which will be widely appreciated. Treatment is very fully dealt with and altogether the book is sure to appeal to a large number of medical men.

PHYSICAL DIAGNOSIS.—By W. D. Rose, M.D. Fourth Edition. St. Louis: C. V. Mosby Co., 1924. Price \$8.50. Pp. 755.

This book is well written, well printed and well illustrated. It has already had a great measure of success, which is probably due in great part to the attractive manner in which the methods of diagnosis are set forth. There are no less than 319 illustrations

in the 755 pages of the book and each of these teaches a lesson.

From the point of view of the Indian student and the Indian medical man it is a drawback that only physical diagnosis is dealt with. Books which deal also with laboratory methods are more in request in a country where the weight and cost of text books are matters of great importance. The medical man who wishes to bring up to date his knowledge of physical diagnosis will find this book just what he requires.

Annual Reports.

ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER OF THE CITY OF BOMBAY FOR THE YEAR 1923. BOMBAY: THE TIMES PRESS, 1924.

This is an ably written and very interesting report. Bombay city covers an area of 23½ square miles and has a population of 1,176,000. In 1923 the recorded birth rate was 17.32 per mille and the death rate 31. This birth rate is phenomenally low and is a usual feature of Bombay vital statistics. The reasons adduced are defective registration of births and the custom whereby married women leave Bombay for their confinements. About 33 per cent. of the infants in Bombay are born elsewhere. About 10 per cent. of the births are unrecorded. Allowance for these two factors raises the birth rate to 28,—still a low figure which points to an actual want of fertility in the women of the city. Most of the births occur towards the end of the year.

The death rate is high, but is about the level of the ante-plague years. It will hardly be credited that 66 per cent. of the population of Bombay live in one-roomed tenements. About 25 per cent. of the deaths are certified by medical practitioners, vaidas and hakims. As elsewhere in India, respiratory diseases top the list as causes of death; congenital diseases and diseases of infancy coming next. Infant mortality is considered in considerable detail. The ratio per thousand reported births was 411. This figure represents an exaggeration; making allowances for unregistered births in the city and for infants born outside the city, a figure of 269 is obtained. Making all allowances, however, the health officer is of the opinion that the infantile death rate of Bombay must be one of the highest in the world. It is high amongst the better classes also and malaria is suggested as the cause. Infantile debility and respiratory diseases account for most of the deaths, 38.8 per cent. of the deaths occur in infants under one month. An excessive infant mortality in Bombay occurs with a high general death rate and fluctuations of the one correspond with fluctuations of the other. The fact noted above that 66 per cent. of the population live in one-roomed tenements explains to some extent the high infantile mortality, which varies inversely with the number of rooms per family.

An interesting description is given of the various measures taken for the preservation of infant life. A complete scheme of voluntary welfare centres, maternity homes, infant milk depôts and municipal nurses exists and should soon effect a considerable improvement.

Epidemic and other diseases.—About 25 per cent. of actual cases were notified by medical practitioners. **Plague.** From February to June this disease assumed epidemic proportions. Inoculation, rat destruction, evacuation and disinfection were the measures adopted. During the months of March, April and May from 5 to 7 per cent. of rats examined were plague-infected. Pesterine is the disinfectant used.

Cholera caused 323 attacks and 189 deaths. The disease was introduced by Mahomedan pilgrims, about 17,000 of whom passed through the city. Inoculation

was of distinct benefit as a preventive; water borne disease could not be definitely excluded and the drinking water supply was chlorinated. This was followed by a distinct fall in the mortality, but the fall was too sudden to be accounted for by the disinfection of the water.

Tuberculosis accounted for 1,371 deaths, of which 1,227 were due to phthisis. An anti-tuberculosis league exists, with 2 dispensaries for out-patients, and a sanatorium with 32 beds. Three nurses are attached to each dispensary for visiting work. There is inadequate provision of hospital accommodation for advanced cases of phthisis. A good start has, therefore, been made for dealing with this terrible problem but naturally housing and economic conditions are very bad enemies at the outset.

Malaria threatens to become a serious menace to the city population and especially to the crews of visiting steamers. Dr. Bentley's work on Bombay malaria is well known: he pointed out amongst other things the dangers of wells as breeding places of *A. stephensi*. Cisterns would now appear to be a serious danger, and also constructional work. *A. stephensi* is the most notable carrier here. The Back Bay reclamation scheme threatened to become a serious danger in regard to providing breeding places for Anopheles and a special sanitary committee has been appointed to look after this area. Several cases occurred where crews of ships after leaving Bombay developed serious malaria, and Lieut.-Colonel S. R. Christophers, I.M.S., was deputed to report on the causative conditions. In his report Colonel Christophers has sounded a note of warning which the authorities and the public will no doubt heed. Wells, uncovered cisterns, and new constructional work all provide suitable breeding places for *A. stephensi* and are a source of danger to the whole of the population, poor and well-off alike. The remedies suggested are covering in of wells and cisterns, the provision of an adequate constant water supply to do away with the necessity of cisterns, and legal powers to enforce constructional works being conducted in areas where other methods cannot control mosquito breeding.

As Colonel Christophers says, "Which is the most dangerous, a heap of rubbish or an uncovered cistern?" Undoubtedly the latter, but the former can be legally dealt with as a nuisance, the latter cannot. A great deal of attention is paid by the malaria department to the stoppage of mosquito breeding. The Back Bay Reclamation Scheme has a special medical officer to look after potential mosquito breeding. The yards of the large railway termini would seem to be danger spots. A summary of the work done during the year points to the energy of the department in anti-malarial measures.

The League for Combating Venereal Diseases is a voluntary agency, with a well equipped dispensary for free diagnosis and treatment. Post-graduate classes for medical practitioners are held three times a year. This is excellent work and will progress. The Corporation maintains twelve municipal dispensaries to administer free relief to the sick poor.

Milk Supply.—Those who know Bombay will remember the great numbers of milk cattle stables from which the milk supply of the city is drawn under conditions anything but sanitary or ideal. These are a menace and a nuisance to the public health and are to be removed to Trombay. In addition, the importation of milk from outlying places is to be encouraged. The amount of milk consumed in Bombay is 3.1 ounces per head. In London the average is 5 ounces and in New York, 11 ounces. The milk available, therefore, is far below the real needs of a vegetarian population. A very real effort is being made to solve the problem of milk supply and this will be watched with interest by other communities in India, especially in the large cities.

Water Supply.—This is insufficient in amount and intermittent in supply. All is unfiltered, but schemes are under consideration for the filtration of all the water, and the construction of the third pipe line from

Tansa Lake is proceeding rapidly and should afford relief.

Conservancy.—The old insanitary basket privies still abound and constitute a very big problem. The present sewer system is inadequate and the scheme for re-modelling and enlarging the whole system is still under consideration.

Housing.—An ambitious scheme for systematising routine inspection of every house is under way; many inspections have been done and a large number of defects remedied.

The City Improvement Trust is gradually demolishing insanitary areas, the inhabitants being transferred to new tenements. A scheme for the construction of 50,000 new tenements for the working classes is under way and if funds are available the whole of the slum areas will be tackled. Already, since 1898, no less than 25,427 new tenements have been provided against 25,955 demolished. The corporation is providing 8,000 tenements for its employees.

These schemes represent great aims and solid achievement. The infectious diseases' hospitals have carried out excellent work. The mortality in cholera cases is now 31.3 per cent. instead of 60 per cent. An outbreak of cerebro-spinal fever occurred but the attempt to determine the type failed as the suitable agglutinating sera were not available.

The food-stuffs examined in the municipal laboratory were mainly milk; of 4,267 samples examined 1,738 or 41.3 per cent. were found adulterated. The amount of chlorine necessary to disinfect the Tansa water was found to be 0.78 parts per million, so that lactose fermenters would be absent in 50 c.c. The time of contact is, however, not stated. The result of the routine bacteriological examination of the Bombay waters is disappointing and the schemes for filtration and disinfection would seem to be thoroughly justified.

The corporation and Dr. Sandilands and his staff are to be congratulated on the able report put forward of a year's hard work on lines at once enlightened and progressive.

A. D. S.

ANNUAL REPORT OF THE HEALTH OFFICER OF THE CITY OF MADRAS FOR THE YEAR 1923. MADRAS: KAPALEE PRESS. 1924.

THIS well-written report describes clearly the vital occurrences and the various activities of the health department of Madras city during 1923. The population of Madras city, which covers an area of 27½ square miles, was 526,911 at the census of 1921. The review of the vital statistics reveals a satisfactory condition during 1923; the birth rate was 43.6 per mille, the death rate 37.8; and the infantile death rate 254 per thousand registered births. The birth rate showed an increase, while the death rate and the infantile mortality rate showed a decrease on the average figures for the previous ten years. It is interesting to compare these figures with those of Bombay which for 1923 showed 17.32; 31; and 411 respectively. There was a notable absence of any epidemic disease. The system of registration has been revised and it is hoped that more correct returns will ensue. The number of still-births seems to be on the increase, the causes adduced being poverty, unhygienic home conditions, and parental disease. Interesting charts display the age and sex distribution of mortality, the greatest mortality being at the extremes of life. The importance of age and sex composition of a population in influencing the general mortality and the birth rate is pointed out. Comparisons of death rates alone of cities like Bombay and Calcutta and Madras as criteria of healthiness would be fallacious. For instance at the age-period 15 to 40, Madras has 1,000 men for every 940 women, while in Bombay and Calcutta the proportions are 1,000 to 360 and 1,000 to 420 respectively, a very great difference. Again at the period 20 to 45 when death rates are low, Madras

has 20 per cent. of such, while the proportion in Bombay and Calcutta is 40 per cent.

The question of infant mortality, its causes and the measures likely to be of use, are fully discussed, and the interesting description given of the child welfare schemes at present in operation reveals the energy and ambition behind this important work. As has been noted in other Indian cities the infantile mortality rate fluctuates or has done so in the past with general mortality rates. It is pointed out that the ordinary infantile mortality rate is composed of two distinct components,—the mortality up to one month after birth, and the mortality from the first to the twelfth month of life. It is the second component which seems to be particularly vulnerable; the first, even in advanced countries, has not been reduced materially; and it is against this component that the energies of ante-natal care and treatment of the mother are particularly directed.

Malaria does not seem to have been a potent cause of general mortality; and only 52 deaths from kala-azar were registered. Cholera occurs in August and December. A reduction in small-pox deaths is noticeable after the heavy toll this disease took of life in 1921. Only one case of plague occurred. Diarrhoea and dysentery occurred to the same extent as in 1921 and the water supply of Madras city would seem to require attention. Diseases due to the tubercle bacillus would appear to be increasing not only in the city but in the province. This is a serious problem in other Indian cities and is largely an economic one. Relapsing fever was present but only claimed two deaths out of sixty-two attacks, a tribute to the efficiency of those responsible for diagnosis and treatment and to those who undertook preventive measures. The number of deaths certified by medical men formed only 12.7 per cent. of the total deaths in the city and the greater proportion of these were certified from public hospitals. In spite of this the health department by its own inspectors maintains the accuracy by a very efficient method of inspection and control. As regards vaccination a disquieting feature is the growing tendency for medical practitioners to give certificates of postponement of vaccination on grounds of health. Trivial complaints are given as excuses for these certificates.

The quality of the drinking water has received attention. A mixture of filtered and unfiltered water is apparently given to the city and the result is naturally not satisfactory.

Anti-malarial measures, especially in regard to insanitary tanks, are hampered by legal restrictions which make practical action nearly impossible. The housing problem exists in Madras as elsewhere. Improvements such as are undertaken by Improvement Trusts are necessary. No Food Adulteration Act is in force yet; this would seem to be an urgent necessity in a city of this size.

The inspection of school premises and school children is being undertaken in a serious manner. Insanitary conditions have been pointed out and a system of postcards introduced by which the information regarding any medical defect, uncleanness, etc., of children, is sent to the parents, with suggestions for remedies; parents were invited to be present at the time of inspection. A striking fact emerging from the inspection is the prevalence of infectious diseases, including skin affections and tuberculosis. Malnutrition is common and the average weight and height is below English standards for the various ages. This is hardly a just comparison, of course.

It is said in Madras that "dental diseases are not so common a feature in this country as in England"; in our experience this is hardly true as a general statement for other parts of India.

The numerous hospitals and dispensaries in the city have achieved much good work throughout the year.

The municipal laboratory was established in 1922 and undertakes the chemical and bacteriological

examination of water and food-stuffs. The bacteriological quality of the drinking water in the city mains was not completely satisfactory. There is an interesting note on the growth of a species of polyzoon in the conduit mains. There would appear to be a very large amount of organic matter in the Madras water. The conservancy bullocks seemed to have suffered from a variety of diseases; trypanosomiasis and multiple abscesses, anthrax and tuberculosis, and foot-and-mouth disease were all prevalent. The fact that 8 bullocks died from tuberculosis is notable.

The report is interesting and deserved better treatment at the hands of the printers and compositors; the number of misprints are so numerous as to be irritating, the page of *addenda et corrigenda* could have been extended, and itself contains two glaring misprints.

A. D. S.

ANNUAL ADMINISTRATION REPORT OF THE ASANSOL MINES' BOARD OF HEALTH, FOR THE YEAR 1923-24. CALCUTTA: JAMES GLENDYNE, LTD., 1924.

THE Asansol Mines' Board of Health is an *ad hoc* authority created by the Government of Bengal by the Asansol Mining Settlement Act (Act II of 1912). The area has a population of nearly 330,000 and consists of mining areas, villages and municipalities. In such a congested area cholera and small-pox and other infectious diseases will tend to be rife, and the Board was created mainly for the prevention and control of these diseases. In Dr. Tomb the Board are fortunate in having an energetic and capable Chief Sanitary Officer, and the report gives ample justification for the creation of the Board, while the statistical figures bear eloquent evidence of the energetic activities of the sanitary staff. An appendix compares the vital statistics of the area with those of Calcutta and Howrah. The death rate during the period under review was 17.97 compared with 28.4 and 28.64 for Calcutta and Howrah. Its cholera incidence is half and its small-pox incidence about one-tenth of the rate of these towns.

The present act does not, however, confer wide enough powers, and it is hoped to have these extended by an act similar to the Bihar and Orissa Mining Settlement Act of 1920.

The Board keeps a careful watch on the villages bordering on its areas, and epidemics in these are promptly checked so that epidemic disease does not enter the area from these sources. The sanitary work covers a variety of objects, the chief perhaps being the suppression of epidemics, and particularly of cholera, the incidence of which compares very favourably with other places; Dr. Tomb places great faith in his essential oils mixture as a preventive and as a curative agent in the early stages of the disease before collapse has set in. It would be interesting to hear of results in other parts of India where it has been tried.

The incidence of small-pox was remarkably low, and 40 out of the 50 cases occurred in outlying villages. Vaccination was widely carried out from house to house free of charge. There was no case of plague or epidemic dropsy and the year was remarkably free from malaria. Respiratory diseases accounted for the greatest number of deaths; a critical analysis of these, if possible, would be interesting. The collection of complete vital statistics is as elsewhere a matter of concern; a reward of two annas to village *dais* for reporting authentic births was not a success.

The infantile mortality rate was 150, a figure that compares very favourably with other areas and towns. An interesting note is given on the work of the malarial investigation staff. *A. rossi* and *fuliginosus* formed the largest number of *Anopheles* species found, with a small percentage of *culicifacies*. An opinion

as to the local carrier would be very interesting. Medical inspection of school children and lectures to the public and to schools form other activities of the Board. The Board and its Sanitary Officer are to be congratulated on the excellent work accomplished. This is an excellent example of what can be done by concentrated continuous action and should act as a stimulus to other local bodies.

Correspondence.

THE CAUSATION OF CANCER.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I have read with much interest a long review of my book "Cancer: How it is Caused, How it can be Prevented," in your November issue. I am glad to see that you consider that the book will be practically useful. Indeed, I have received hundreds of letters from doctors and non-doctors spontaneously thanking me and telling me that adoption of my suggestions has been followed by vast benefit in health. While praising the various reforms urged in my book, you not unnaturally express doubt as to my analysis regarding the origin of cancer. Your scepticism is perfectly justified in view of the numerous loudly advertised cancer "cures" which have proved disappointing. I am sure that you and your readers will be glad to hear that I have received invaluable corroboration of my views since the publication of my book.

My thesis is that cancer is a disease of civilization, that it is practically unknown among primitive races leading primitive lives, and that it is due to chronic poisoning and vitamine starvation, to wrong living, that it is more frequent in the towns than in the country, more in evidence among the rich than among the poor.

My statement as to cancer being practically unknown in the wilds has lately received confirmation from a great many quarters. For instance, Lieut.-Colonel H. Hallilay, I.M.S., has informed me that he has been practising chiefly among the Himalayan hill-men for more than twenty years, that they do not suffer from cancer and its allied troubles such as gastric and duodenal ulcer, appendicitis, colitis, etc., that he has performed an enormous number of operations on these people, among them 700 for stone in the bladder, but that he has had not a single operation for an internal cancer, although a great many of the hill-men live to an advanced age. Other informants have sent me similar data. Cancer is a disease of civilization, and a few exceptions in the wilds merely confirm the rule.

The fact that arsenic, aniline and various other virulent poisons may lead to cancer after twenty years or more if absorbed continuously in infinitely small doses is shown by hundreds of examples in my book. Burn has an effect practically identical to poison, as I have shown by giving details of scientific experiments. A severe x-ray burn, like severe poisoning with aniline or arsenic, does not lead to cancer, but more or less continuous burning, though ever so slight, is apt to be followed by cancer, as a rule after ten years or more. Chronic poisoning by chronic burning is furthermore shown in the case of *kangri* cancer and of cancer of the oesophagus and stomach. We unfortunate civilised people drink our tea, etc., at 150°, while our bath is only 105° or 110° at most. Chronic poisoning from the bowel is one of the most frequent sources of cancer, but the outbreak need not be in the bowel itself. Cancer being a blood disease, the outbreak is likely to occur at some weakened spot, such as the breast or the uterus. In the overwhelming majority of cancer cases which I have investigated, the

cause can clearly be traced to chronic poisoning in some form or other, and vitamine starvation favours chronic poisoning inasmuch as it weakens the body in general, as it causes constipation and as it leads to lesions in the bowels through which the toxins are readily absorbed into the body. The fact of vitamine starvation bringing about these lesions has been brilliantly proved by the experiments of Colonel McCarrison.

The richer the people are, the more refined, the more concentrated, the more manipulated and the more denatured is the food they eat. The wealthy suffer most intensely from vitamine starvation, from constipation and auto-intoxication consequent upon it, and from protein poisoning. To-day a gentleman came to me and told me that his wife had died from cancer three months ago, that he had read my book, that in her case my analysis was wrong, that the lady was not constipated, that she had led a regular and normal life. Enquiry elicited that the victim had lived on the richest and most concentrated foods. She ate meat three times a day, never ate raw fruit and salads, and she took practically no exercise. Although she had an evacuation every morning her bowels were probably always filled with putrid flesh eaten several days ago.

In lunatic asylums, homes for the aged, convents, monasteries, etc., the cancer death rate is extremely low. I do not wish to encroach upon your space by proving that point in detail. But then the inmates of these public institutions are plainly and rather poorly fed. They eat large quantities of vegetables of their own production, very small quantities of fresh meat raised in the neighbourhood, and tea, porridge, etc., is never piping hot, to the dissatisfaction of newcomers. "Scientific" foods and chemically preserved food, foods which have been deprived of vitamines and mineral salts, are practically unknown in those institutions and adequate exercise promotes the expulsion of the cancer poisons by skin, bladder and bowel. Among the hard working agricultural labourers and coal miners who perspire profusely and who work in a stooping attitude which promotes persistalsis, the cancer death rate is extremely low in England, but among their wives, who potter about the house, it is very high.

It seems to me obvious that cancer is a disease of wrong living and that it can be eliminated by right living, and this view is being held more and more widely among experienced medical men who have read my book.—Yours, etc.,

J. ELLIS BARKER.

ALBION LODGE,
FORTIS GREEN, LONDON, E.2.

THE BERIBERI PROBLEM: A CORRECTION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the article by Major R. N. Chopra, I.M.S., and myself in your issue for last January, will you very kindly publish this letter in your next issue to correct the clerical error which was made in stating that "Fraser failed to produce beriberi in prisoners fed on polished rice." It is, of course, well known that Fraser and Stanton, 1909 (*Lancet*, Vol. I, February 13th), clearly showed that white rice was concerned in the production of beriberi.—Yours, etc.,

H. W. ACTON,
Major, I.M.S.,

CALCUTTA SCHOOL OF TROPICAL MEDICINE,
6th February, 1925.

INTRAMUSCULAR QUININE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In a recent publication—(*Indian Journal of Medical Research*, Vol. XII, No. 2, October 1924)—

two well known members of the staff of the Calcutta School of Tropical Medicine made the categorical statement that the intramuscular injection of the salts of the alkaloids derived from cinchona bark should be considered as malpraxis, and that the "only one method" of administering the cinchona alkaloids is by the mouth.

It is, however, admitted by them that "very rarely" in grave cases, e.g., cerebral malaria, when an immediate action is required, quinine base should be injected intravenously.

That the administration of quinine intramuscularly has been practised too extensively is admitted by many, and the exact work of Majors H. W. Acton and R. N. Chopra, I.M.S., should have a deterrent effect on those who, in the past, have systematically pumped these irritant and tissue-destroying substances into the depths of the muscles without pausing to picture mentally the local necrosis which inevitably results.

There are, however, a number of cases in which it is practically impossible to administer the necessary drugs either by the mouth or by the intravenous method, and in which it is of the utmost importance to use the intramuscular route.

In very young children it is often exceedingly difficult or impossible to find a suitable vein. Young children, unfortunately, are apt to be unable to retain quinine if given by mouth during the first few days of a malarial attack, particularly if there is frequent vomiting and general gastro-intestinal disturbance, as is not uncommonly the case. My experience has been that intramuscular injections of quinine bihydrochloride in such cases have resulted in very great benefit to the patients concerned.

In a small number of persons, particularly stout, middle aged females, it is quite impossible for even those most experienced in intravenous therapy to be able to find a suitable vein for purposes of injection, and if such persons are attacked by malaria, with frequent vomiting, one has to decide between exposing a vein by incision and the administration of an intramuscular injection and, except in desperate cases, the latter method is the lesser of two evils.

It cannot be doubted that the indiscriminate use of the intramuscular method of administering quinine is strongly to be deprecated on account of the very definite risks if the most scrupulous care is not taken to ensure the sterility of the syringe and of the injected fluid; but, on the other hand, the sweeping assertions made by Majors Acton and Chopra are liable to induce practitioners to deprive certain cases of a most valuable method of treatment.

The term malpraxis is an ugly one with a very definite legal significance. It should not be used lightly and certainly not in connection with a method which most of us have been taught to use, with discrimination by those most eminent and experienced in the practice of tropical medicine.

It is to be hoped that, bearing in mind the warnings of Majors Acton and Chopra with regard to the ease with which the necrotic areas become infected by pathogenic organisms and guided by their work in the choice of a suitable preparation, practitioners will continue to use intramuscular injections when indicated.

—Yours, etc.,
G. R. McROBERT, M.D., M.R.C.P. D.T.M. & H.,
Capt., I.M.S.
DERA ISMAIL KHAN,
8th December, 1924.

INTRAVENOUS IODINE INJECTIONS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Ever since the advent of an article by Lieut.-Colonel W. W. Jeudwine, I.M.S., on the therapeutic value of intravenous iodine injections (*Indian Medical Gazette*, December 1923), quite an avalanche of letters and articles has appeared on the subject. I personally

drew attention to the value of this drug in septic conditions in 1921 (*Indian Medical Gazette*, October 19, 1921) and have had a long record of success ever since in many other infections. My case of severe pyæmia was mentioned in your issue for April 1922, p. 151.

My latest successes with intravenous iodine treatment have been four cases of pneumonia. My largest dose in a pneumonia case has been 60 m.; and that has been as a third injection. I now never use less than 20 m. in 10 c.c. of normal saline for a first dose, in whatever affection I am using the drug; and according to the reaction obtained increase by 10 m. or 20 m. for subsequent doses.

I have for long now discontinued the use of the B. P. tincture for an aqueous solution, which does away with the fear of thrombosis, and I offer this advice to others using iodine intravenously.

In pneumonia although the disease is not cut short, the grave and distressing symptoms are quite abolished, the ratio between pulse and respiration is maintained, and dyspnoea is scarcely ever noticed, while resolution once started is rapid.

Last month in a case of acute rheumatic fever I had most gratifying results. The fever fell to normal after the first injection, and resolution in the affected joints with loss of pain was established in 36 hours.

—Yours, etc.,

A. BAYLEY DE CASTRO,
Junior Medical Officer,
Haddo, Port Blair, Andaman Isles.

PORT BLAIR,
27th November, 1924.

[NOTE.—We do not know who was the first doctor to use iodine intravenously. It could not have been Hippocrates, since the element was as yet undiscovered in his day; but the method dates very far back. We believe that Lieut.-Colonel F. P. Connor, D.S.O., I.M.S., was the first surgeon in India to use it systematically, at first in cases of plague, and later in surgical sepsis, from about 1910. The special value of Colonel Jeudwine's article was that it constituted a review of a very large series of cases, gave a detailed technique, and a collected volume of evidence in favour of the method.—EDITOR, I.M.G.]

A YOUNG DOCTOR'S VIEWS OF OLD DOCTORS.

WE have received a very interesting letter from a young doctor in the Madras Presidency. He points out that the older doctors are useless and that their interests lie chiefly in the study of regulations. They are addicted to the monotonous repetition of quinine mixture. In short, the old doctors are expensive nuisances who ought to be superannuated at once to make way for the younger and more enthusiastic men.

The future of medicine in Madras must be bright indeed if the young doctor's picture of the junior medical men is a true one. They are full of zeal and energy, their eyes are glued to the microscope and when they hear that one of the old doctors is engaged in murdering a patient they at once rush to the help of the victim and in due course save his life. Apparently these young men have already secured lucrative practices as is only right, but they cannot bear to see the terrible waste of Government money, and they are prepared instantly to take the places which will be vacated when the old stagers of forty and fifty are consigned to a well-merited or forcible retirement.

The last words of the letter will show the drift of the argument. They are:—"With the money saved by the compulsory retirement of the 'seniors' double the number of young active and fresh men may be employed, and thus the quality of work turned out by the subordinate medical officers considerably improved and the popularity of the allopathic dispensaries revived and enhanced. Let us hope that everything will turn out in our favour."

We have derived considerable satisfaction from reading this letter which is like a cool breeze on a stifling day. Surely the time is not far distant when the young medical men will assert their rights, if necessary by the use of some really modern method such as the "death ray" of the great Grindell Matthews.

There is only one thing that distresses us. We hope that our correspondent does not seriously propose the revival of the obsolete "allopathic system." We have no more desire to see it rise from the grave than to see restored to life other relics of antiquity like the Ayurvedic and Unani systems. Modern scientific medicine holds no brief for any "system."—EDITOR, I.M.G.

YAWS IN INDIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—One frequently comes across remarks in medical journals or books that frambæsia or yaws is very rarely, if at all, seen in India. Thus Dr. H. T. Holland, in describing his case of gangosa in Baluchistan, in your issue for last August, writes that yaws is very rare or unknown in that part of India. Dr. Manson-Bahr remarks, however, that "the exact distribution of yaws in India and China is unknown."

Travancore is a very progressive modern native State in the south of India, maintaining a considerable number of district hospitals and dispensaries. In central Travancore, I am well acquainted with about a dozen *taluks* in which large numbers of cases of yaws are being admitted to the district hospitals and dispensaries. Although my experience of other *taluks* is not sufficient upon which to base personal evidence, yet a number of my colleagues have informed me that yaws is relatively common in out-patient work in this State; so much so, indeed, that a stock "yaws" mixture is in general use, which contains antimony tartrate.

As regards the diagnosis of the disease, one cannot err, as the typical scab, mode of infection, constitutional changes and the nature of the big and ugly scars and deformities formed after healing of the lesions are very characteristic. In two or three hospitals which I have visited cases of yaws present themselves as out-patients almost every day. The disease is generally met with in low-class people of dirty and insanitary habits.

Yaws is at least not rare in Southern India.—Yours, etc.,

M. A. KRISHNA IYER, L.M.P.

NATCHARKOIL, TANJORE DISTRICT.
1st December, 1924.

DIARRHŒA IN THE BREAST-FED INFANT.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Since your publication of my article on the "Digestive Ailments of Children" in your March 1924 number, I have been inundated with hundreds of enquiries from practitioners all over India as to the correct treatment of that devastating condition—the green or yellow diarrhœa of the breast-fed infant. May I, therefore, thank the hospitality of your correspondence columns to answer these enquiries, for it is in the hot months that this condition is most serious.

I have been investigating these cases for many years, and find that the analyses of the breast milk, and infants' stools and urine, prove that in 70 per cent. of cases excess of carbohydrates or fat is the cause; and of the remaining 30 per cent. of cases, in 25 per cent. excess of protein is at the root of the trouble.

I lay stress on this subject because my experience as a consultant convinces me that, since its pathology is not understood by practitioners, many of these infants die, others are ill for weeks, whilst others are rapidly and unwisely taken off the mother's milk and

put on to some proprietary milk food, with the result in some, of acute gastro-enteritis, acidosis, and death; in others, eventually the whole gamut of symptoms of rickets or chronic gastro-intestinal catarrh supervenes.

My investigations have taught me that any drug, and especially grey powder and castor oil emulsion, is bad medicine and worse practice. What you must do is:—

(1) See that the nipples are kept scrupulously clean before and after each feed; and the mouth of the infant kept clean.

(2) Have the baby fed at both breasts for 7 minutes three hourly, and *before* it is put to the breast give 1 oz. of boiled water in which 5 grains of bicarbonate of soda have been dissolved.

(3) Between the feeds give a solution of $\frac{1}{4}$ per cent. sodium bicarbonate and $\frac{1}{4}$ per cent. saline solution, as much as desired, making it palatable with a fractional quantity of saccharine. Perhaps I need not remind your readers that $\frac{1}{4}$ per cent. is roughly a quarter of a teaspoonful to the pint of boiled water. If any œdema occurs stop the saline but go on with the sodium bicarbonate.

(4) The mother is to avoid constipation, and regularly drink a whole tumbler of water before each breast feed is due.

(5) She should not take in excess those things beloved of nurses, i.e., cotton seed, vast quantities of milk, sago, and the like, which only cause distension and constipation; for remember that the best galactagogue is the hungry infant fed at regular 3 hourly intervals.

(6) Each breast should be hot and cold sponged for a quarter of an hour twice daily, and gently massaged from the periphery to the nipple twice daily. She should rest on her bed from 12 noon to 3 p.m.

(7) Weigh the infant regularly before and after each breast feed at 6 a.m., 9 a.m., and 12 noon, and at 3, 6, and 9 p.m. for a few days, and check on a chart the gain in weight per feed. You will frequently find that the child is taking less, or more, at one or more feeds per day than at others. If less than it should be, you must supplement that feed with whey, or skimmed milk and water. For the first month dilute such milk 1 in 2, for the second month 1 in $1\frac{1}{2}$, and for the third month 1 in 1. The best diluent is boiled water (but if the child is debilitated clear whey is better than water as a diluent), sugar of milk half a teaspoon to 3 ozs. being added. If the gain is more than it should be at one feed, all that is necessary is to lessen the time at the breast.

On these lines you will rarely find it necessary to take the infant off the breast.

(8) If the case is an advanced one when you see it, you may do as above, or you may supplant one or two breast feeds by whey or skimmed milk, remembering that the stomach of an infant will not hold a greater quantity than 1 oz. over its age in months, e.g., if the baby is 4 months old 5 ozs. should be its feed.

(9) For the frequent small green slimy stools a warm water enema is often most useful.

If the buttocks are scalded, equal parts of zinc oxide and castor oil applied locally will allay the soreness.

(10) If the condition is a green lienteria,—that is the infant's bowels are moved immediately following its feed—2 to 5 drops of tinct. camph. co. before each feed will be found useful.

(11) Remember that a reliable pair of scales is the most important thing in prognosis and treatment.

(12) Comprehension of the pathology and treatment by the doctor, combined with confident co-operation on the part of the mother, is essential to success.

(13) Remember that breast feeding is Nature's provision. Next best to this is cow's or goat's milk. Never give proprietary milk foods if you would avoid rickets, spasmophilia, and gastro-intestinal complaints.

To take any infant off the breast, is, in nine cases out of ten, not only a grave error and responsibility,

but an insult to Nature and an aspersion on the knowledge of the practitioner.—Yours, etc.

V. B. GREEN-ARMYTAGE,
Major, I.M.S.

CALCUTTA,
14th January, 1925.

THE SHORT TERM COURSE: CALCUTTA SCHOOL OF TROPICAL MEDICINE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I shall be very glad if you kindly publish the following in your esteemed journal:—

The students who attend the 6 months' course in the Calcutta School of Tropical Medicine and pass the examination, obtain the Diploma in Tropical Medicine, and they can style themselves D.T.M. (Bengal). But those who attend the 3 months' course and pass the short course examination are granted a certificate only. They cannot use any title for their additional qualification. I would therefore submit the following for the consideration of the Faculty of Tropical Medicine and Hygiene, Bengal:—

That the students who attend the short course in tropical medicine and pass the examination, be granted a Licence in Tropical Medicine and Hygiene and they be permitted to style themselves "Licenciate in Tropical Medicine and Hygiene," L.T.M. & H. (Bengal), just as those passing the long course examination are entitled to style themselves D.T.M. (Bengal).—Yours, etc.,

A. PAUL,
Sub-Asst. Surgeon,
Certificate holder in Tropical Medicine
and Hygiene.

MAHIMAGANJ, RANGPUR,
9th November, 1924.

BRITISH INCOME-TAX REFUNDS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—It does not appear to be generally known that claims for refund of British income-tax deducted from dividends, interest, rents, etc., received from Great Britain can now be made for the whole period since April 5th, 1920.

Formerly claims for recovery of tax were limited to three years. Now, however, under the Finance Act, 1923, this time limit has been extended to six years, but not so as to affect any years previous to 1920.

I might also point out that it makes no difference whether the income in question is derived from trustees in Great Britain, as in all cases a refund can be claimed.

I have gone into the matter very fully with the Inland Revenue lately, and if any of your readers are not aware of what claims can be preferred and will get in touch with me at 13, Buckingham Palace Gardens, London, S.W.1, I shall be happy to advise them.—Yours, etc.,

WILFRED T. FRY.

13, BUCKINGHAM PALACE GARDENS,
LONDON, S.W.1.
25th October, 1924.

Service Notes.

APPOINTMENTS AND TRANSFERS.

The services of Colonel R. A. Needham, C.I.E., D.S.O., M.B., I.M.S., Deputy Director-General, Indian Medical Service, are placed at the disposal of the Railway

Department (Railway Board) for a period of one year, with effect from the 1st January, 1925.

Lieutenant-Colonel F. P. Connor, D.S.O., I.M.S., Professor of Clinical and Operative Surgery, Medical College, Calcutta, is appointed to officiate as Professor of Surgery of the Institution and Surgeon to the Medical College Hospitals, *vice* Lieutenant-Colonel R. P. Wilson, F.R.C.S., I.M.S., with effect from the date on which he took over charge.

Lieutenant-Colonel H. B. Steen is appointed to officiate as Professor of Clinical and Operative Surgery, Medical College, Calcutta, and Surgeon to the Medical College Hospitals, *vice* Lieutenant-Colonel F. P. Connor.

Lieutenant-Colonel J. Masson, M.B., F.R.C.S.E., I.M.S., is appointed to officiate as Inspector-General, Civil Hospitals, Bihar and Orissa, with effect from the 13th March, 1925.

Lieutenant-Colonel J. K. S. Fleming, O.B.E., I.M.S., is appointed Deputy Director-General, Indian Medical Service, with effect from the 1st January, 1925.

Lieutenant-Colonel J. D. Graham, C.I.E., M.B. I.M.S., officiating Public Health Commissioner with the Government of India, is confirmed in the appointment with effect from the 1st September, 1924.

Lieutenant-Colonel E. O. Thurston, Civil Surgeon, Hooghly, was appointed to act as Civil Surgeon, Serampore, from the 12th August to the 20th August, 1924, in addition to his own duties.

Major G. M. Millar, O.B.E., I.M.S., is appointed sub-stantively to be an Agency Surgeon under the Government of India in the Foreign and Political Department, with effect from the 3rd October, 1924.

The services of Major S. Gordon, M.C., I.M.S., are placed at the disposal of His Excellency the Commander-in-Chief, with effect from the date on which he reports himself for duty to the military authorities.

LEAVE.

Colonel H. Ainsworth, M.B., F.R.C.S., I.M.S., Inspector-General of Civil Hospitals, Bihar and Orissa, is granted leave on average pay for 5 months and 24 days and leave on half average pay for the remaining period up to a maximum of 8 months' leave in all, with effect from the 13th March, 1925, or the date on which he avails himself of the leave.

Lieutenant-Colonel J. B. D. Hunter, O.B.E., I.M.S., an Agency Surgeon, is granted leave on average pay for 7 months under the Fundamental Rules, with effect from the 20th October, 1924.

In modification of the orders already issued, Lieutenant-Colonel W. W. Jeudwine, C.M.C., I.M.S., Civil Surgeon, Simla West, is granted leave on average pay for 5 months and 19 days with effect from the afternoon of the 8th October, 1924.

In modification of this department notification No. 2856-Medl., dated the 15th November, 1923, granting combined leave for twelve months to Major E. W. O'G. Kirwan, I.M.S., First Resident Surgeon, Presidency General Hospital, Calcutta, the period of five months from the 6th February to the 5th July, 1924, both days inclusive, was commuted into study leave.

RETIREMENTS.

Lieutenant-Colonel Albert Elijah Walter, O.B.E. Dated 1st February, 1925.

Major A. E. Grisewod, I.M.S. Dated 10th December, 1924.

RESIGNATIONS.

Captain Arthur Leonard Watts, M.B. Dated 31st December, 1924.

Captain Muthu Ramkrishna Grandhi. Dated 1st September, 1924.

PROMOTIONS.

Captain (now Major) G. F. Graham, I.M.S., to be acting Lieutenant-Colonel while commanding No. 1, Combined Field Ambulance in East Africa from 16th April, 1917 to 2nd November, 1917 (inclusive).

NOTES.

DIVISION OF TROPICAL MEDICINE AND
HYGIENE.

THE following medical officers passed the School examination at the termination of the 76th session (September-December, 1924):—

Passed with distinction:—

O'Flynn, J. A.—Winner of "Duncan" medal.
Dye, W. H.
Shelton, C. F.
Hynd, D.
Meek, A. I.
Banerjee, T. N.

Passed:—

Suri, P. N.	Given, D. H. C.
Griffin, R. G.	Sweet, R.
Mallory, J. R.	Morton, Miss U. F. M.
Watkins-Pitchford, H. O.	Williams, A. D.
Caldwell, Miss H. M.	Hacker, H. P.
Khosla, R. N.	Naudi, J.
Grant, R. K.	Navaratnam, S. L.
Young, D. Murray.	de Silva, D. M.
Quin, H. C. E.	Mankarius, A. Y.
Gohar, M. A. El. H.	Harley-Mason, R. J.
Louw, G.	Smith, P. H. S.
Follit, H. B.	Batra, K. R.
de Bono, M.	Newton, I.
Robinson, G.	Wall, A. E.
Campbell, R. F.	Khan, S.
Kahawita, D. L. J.	Lonie, T. C.
Lang, Milton C.	Evans, E. H.
Closson, Miss E. M.	Chappel, Miss M. C.
Goldberg, H.	Bradbury, W.
Hopkinson, H. C.	Bartholomeusz, W. A.
Gill, C. E. G.	Sammons, Miss M. G.
Cassidy, M. A.	McKernan, F.
Hart, W. H.	

16th December, 1924.

THE BRITISH EMPIRE EXHIBITION 1924.

Mav and Baker's Exhibit.

THE reputation which the manufacturers of the well-known "Planet Brand" of fine chemicals and medicinal products have attained is fully upheld by their handsome exhibit. The specimens shewn are all of the firm's manufacture and are guaranteed to have been drawn from their ordinary stock.

A case containing antisyphilitics occupies a prominent position. The compound *Novarsenobillon* is well-known, and maintains its reputation as second to none in all-round efficiency. *Arsenoargenticum* (Sodium Silver Arsenobillon) and the bismuth compounds *Luaton* and *Rubyl*, are also shewn. The two last-named, though in general less effective than arsenical compounds, have sometimes succeeded where both arsenic and mercury have failed.

A product interesting to overseas practitioners is *Stovarsol*, an organic arsenical compound which is taking a foremost place as the most effective remedy in amoebic dysentery, and has had marked success in yaws. Good results have also been obtained in the treatment of lamblasis. The marked parasitocidal properties of *Stovarsol*, are due to its high arsenic content, notwithstanding which it is of very low toxicity to the human organism. It is supplied in tablets for oral administration, which renders it most convenient in use.

Special reference should be made to a new hypnotic and analgesic brought forward under the name of *Soneryl*, a product of proved efficiency, possessing

the important advantage of causing no deleterious after-effects.

The manufacture of bismuth salts forms a most important branch of the firm's activities. A wide selection is shewn, specially prominent being a large show-jar of bismuth carbonate. This is extraordinarily light and impalpable, a property which is indispensable for medicinal use in view of the mechanical action of the product in protecting the digestive tract from irritation.

Mercurials form an imposing display in a large case made for the *Exhibition of Industries of all Nations* held in Hyde Park, London, in 1851. The large variety shewn illustrates the wide range of these products manufactured by the firm.

A brilliant display of *Camphor* in cubes, in coloured transparent airtight wrapping, is arranged in pyramids of red, white and blue. The transparency of the *Camphor* has been most effectively preserved.

A special case is given to *Strychnine* and its salts of which the firm make immense quantities. The excellence of the crystals provoked much comment.

Baker's anæsthetic ether, also *Chloroform*, which enjoy an unexcelled reputation for purity and effectiveness are represented by bottles carrying the firm's distinctive label.

A feature which has arrested the attention of many observers is a selection of old containers, including jars, pots, and bottles belonging to past centuries in British history, and also to ancient times, reaching back even to 2500 B.C. These furnish interesting comparisons between products of ancient and modern times.

The very large number of other products shewn include *Scale Preparations*, *Citrates*, *Tartrates*, *Alkaloids*, and other compounds for both medicinal and industrial purposes, which by reason of their excellence have attained a world-wide reputation.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints of the literary pages of the "*Gazette*" gratis, if asked for at the time of submitting their manuscripts.

REPRINTS OF THE ARTICLE CONCERNED (ONLY), IN PLACE OF REPRINTS OF THE WHOLE OF THE LITERARY MATTER OF THE ISSUE, CAN BE SUPPLIED ON PAYMENT IF ASKED FOR AT TIME WHEN ARTICLE IS SENT IN. BUT AS THESE HAVE TO BE MADE UP SEPARATELY, THEY ARE NECESSARILY DELAYED.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

COMBINED CARBON TETRACHLORIDE AND OIL OF CHENOPODIUM IN THE TREATMENT OF HOOKWORM DISEASE.

A REPORT ON THE TREATMENT OF 70 CASES.

By ASA C. CHANDLER, Ph.D.

and

A. K. MUKERJI, M.B.

(From the Hookworm Research Laboratory, Indian Jute Mills Association Endowment, Calcutta School of Tropical Medicine and Hygiene.)

WITH the introduction of carbon tetrachloride in the treatment of hookworm infections, interest in oil of chenopodium and its active principle, ascaridol, has decreased. Nearly all of the extensive tests which have been made on carbon tetrachloride have been made in countries where *Necator americanus* constitutes the great majority of hookworms harboured, and that carbon tetrachloride is more effective against this worm than is oil of chenopodium has been conclusively demonstrated. In the few instances in which carbon tetrachloride has been tested on patients harbouring a considerable proportion of *Ancylostoma duodenale* (e.g., Sawyer and Sweet, 1924; Cadbury, 1924; and Chandler and Mukerji, 1925) it has been shown that its efficiency against this worm is markedly lower, and usually less than is the case with oil of chenopodium. It has also been shown that carbon tetrachloride is much less effective against *Ascaris* infections than is oil of chenopodium.

For these reasons a number of workers have experimented with a combination of carbon tetrachloride and oil of chenopodium or ascaridol. Smillie and Pessoa (1922) found that neither drug increased the toxicity of the other and that their actions were complementary to each other, the carbon tetrachloride being especially active against female hookworms (*Necator*) and the ascaridol against male hookworms and *Ascaris*. They recommended 2 c.c. of a three-to-one mixture of carbon tetrachloride and ascaridol. Lambert (1923) having had several fatalities after carbon tetrachloride treatment of patients harbouring numerous *Ascaris*, and suspecting the possibility of the latter having been in part responsible, tried a combination of 10 parts carbon tetrachloride in the usual dosage of 3 to 4 c.c. with one part of oil of chenopodium, and was well pleased with the results obtained. Bercovitz (1924), in China, adopted Lambert's method and considers it safe and effective, and states that numerous *Ascaris* are expelled by it. Lambert later (1924) tried a combination of four parts of carbon tetrachloride to one part of ascaridol, and considers this the best anthelmintic yet found for mixed hookworm and *Ascaris* infections. Reed (1923), in Borneo, gave 60 minims of

carbon tetrachloride with one c.c. (16 minims) of oil of chenopodium and $\frac{1}{2}$ an ounce of liquid paraffin. He says this practically never fails to remove *Ascaris* and believes it to be more effective for hookworms than carbon tetrachloride alone. Kehrer and Soemadijono (1923), in the Dutch East Indies, recommend a mixture of four to five c.c. of carbon tetrachloride and 1.5 c.c. of oil of chenopodium as being the most effective combination. Soper (1924), in Paraguay, tried 2.4 c.c. of a combination of three parts carbon tetrachloride and one part oil of chenopodium on 40 heavily infected cases; he obtained 10 per cent. of worm-count cures and 35 per cent. of microscopic cures (Willis' method) and a removal of 96.5 per cent. of worms. He considers this treatment very effective in places where *Necator* is the predominant worm. The work of Sawyer and Sweet (1924), in Australia, constitutes the only contradictory evidence; their results, on groups of 24 patients each, showed a lower percentage of cures and of worms removed after treatment with a combination of 5 c.c. carbon tetrachloride and 0.75 c.c. oil of chenopodium than with either carbon tetrachloride (5 c.c.) or oil of chenopodium (1.5 c.c. in 3 divided doses) alone.

At the Carmichael Hospital for Tropical Diseases in Calcutta 22 patients were treated with a combination of 50 to 60 minims of carbon tetrachloride and 10 to 15 minims of oil of chenopodium, by Dr. J. Borland McVail, in 1922. The excellent results obtained by him, together with the favourable reports from elsewhere, stimulated us to try a combination of these two drugs on a further series of cases. Dr. McVail gave the chenopodium in a capsule, accompanied by the carbon tetrachloride in water and followed by one ounce of saturated magnesium sulphate two hours later. In our further series of cases the same method was used except that the carbon tetrachloride was administered in milk, this having been found to be the best method of administration (Chandler and Mukerji, 1925).

Practically all the cases with which we have to deal are lightly infected; the highest number of worms recovered from any one case in the present series was 94, and in most cases it has been less than 50 and in many of them less than 10. Our experience corroborates that of Darling, Soper and others that the percentage of worms removed in light infections is lower than in heavy infections; and we have found that the percentage of worms removed in light infections, by an initial treatment, varies greatly in different individuals from 100 per cent. to less than 20 per cent., regardless of the treatment used. In one case, for instance, which was treated twice with 70 minims of carbon tetrachloride, 21 ankylostomes were removed by the first treatment and 118 by the second. In one case treated by a combination of carbon tetrachloride and chenopodium, 8 ankylostomes were removed by the first treatment, and 39 by the second. Furthermore,

worms are sometimes passed later than three or even five days after treatment, and we are convinced, in spite of all precautions which we have found practical, that stools of hospital patients are sometimes lost. Since all of these factors tend to reduce the accuracy of data on percentage of worms removed, and since it is our experience that the percentage of worms removed increases concomitantly with the percentage of absolute cures, at least in light cases, we think the percentage of microscopic cures is the better criterion of the effectiveness of anthelmintics in these light cases, and have based our conclusions on this. Our criterion of cure has been a series of at least six negative examinations by the Kofoid and Barber technique, the last one being at least 15 days after treatment. Some of the earlier cases in which this rigid criterion was not followed, but in which the evidence indicated a possible microscopic cure, are classed as uncertain cures.

Seventy cases in all have been treated in the Carmichael Hospital with a combination of carbon tetrachloride and oil of chenopodium, on the basis of 60 minims of the former to 15 minims of the latter for a normal adult. Of these cases 41 were pure *Necator* infections, 11 pure *Ancylostoma* infections, 6 mixed infections, and 12 of undetermined species. The following chart shows graphically the percentage of cures obtained in these various groups by the combination treatment, as compared with various methods of administration of carbon tetrachloride and oil of chenopodium.

CHART I.

A comparison of the results of various methods of administration of Carbon tetrachloride and Oil of Chenopodium on *Necator*, *Ancylostoma* and Mixed Infections. N = Pure *Necator*. A = Pure *Ancylostoma*. M = Mixed infection. ? = Undetermined species. Solid black indicates percentage of certain cures. Stripes indicate additional possible cures.

CCl₄ 60 mins. in milk; Chen. 15 mins. in capsule; salts after two hours.

CCl₄ 70 mins. in milk, salts after two hours.

CCl₄ 70 mins. in milk, no purge.

CCl₄ 70 mins. repeated next day; with or without purge.

CCl₄ 70 mins. in 1 oz. sat. mag. sulph. sol., repeated next day.

CCl₄ 70 mins. in water, no purge.

Ol. Chen. 30 mins. in 3 divided doses of 10 mins. each 1 hour apart. Salts after two hours.

It will be observed that the percentage of cures obtained by 70 minims of carbon tetrachloride in milk followed by salts two hours later is higher for *Necator* infections than by any other method, but that the combination treatment comes next. On the other hand it will be observed that the percentage of *Ancylostoma* cases cured by the combination treatment is strikingly higher than with any other method. Only six cases of mixed infections were treated, none of which were cured, but it is significant that in only one of these mixed cases were any ankylostomes passed after the first treatment, whereas after carbon tetrachloride the *Necators* always tend to be eliminated first. Only 22 cases have been given second treatments, and only six of these were cured, four of them pure *Necator*, one *Ancylostoma*, and one undetermined infection. Nine *Necator*, one *Ancylostoma*, four mixed, and two undetermined cases failed to clear up on the second treatment. Of seven cases given a third treatment, one *Necator*, and one mixed (now pure *Necator*) infection were cured, whereas three *Necator*, one mixed, and one undetermined infection were still positive. One of the *Necator* infections cleared up after the fourth treatment.

Since all of our cases which were harbouring *Ascaris* were treated by another method we have no data on the efficiency of this treatment in curing *Ascaris* infections, but the testimony of others already quoted leaves little room for doubt but that it is highly effective.

As regards effects on the patients, we have observed very few symptoms, less in fact than in patients treated with 70 minims of carbon tetrachloride alone. The usual slight giddiness which ordinarily follows the administration of carbon tetrachloride has apparently been absent in many of these cases, and in only one instance has vomiting occurred immediately after administration. Many patients, however, vomited after the magnesium sulphate had been given. No prolonged nausea and no toxic symptoms have been observed. We are convinced that the usual dosage of carbon tetrachloride, 3 to 4 c.c., is quite as safe when given with 15 minims of chenopodium as without it.

From the results we have obtained we do not think that the addition of chenopodium to carbon tetrachloride is of any value in pure *Necator* infections, but the evidence, so far as it can be judged from a small number of cases, is strong that the combined drugs have a considerably more powerful effect on *Ancylostoma* than has either drug alone. In places where *Ancylostoma* and *Ascaris* infections are common, therefore, we agree with Lambert, Reed, Bercovitz and others that a combination of carbon tetrachloride and oil of chenopodium is the best anthelmintic to use. The dosage we have employed, of 60 minims of carbon tetrachloride in milk and 15 minims of oil of chenopodium in a capsule, we consider safe for controlled patients; for field work on a large scale a smaller dose of these drugs in the same proportions might be preferable. It is significant, however, that the fatal cases of carbon tetrachloride poisoning have always followed small doses, indicating, as we have pointed out before, that the condition and diet of the patient is a more important factor than the size of the dose.

CLINICAL STUDIES ON DIGITALIS IN BENGAL.

By S. C. BOSE, M.B., M.R.C.P. (London), D.T.M.
 (London),

Physician, Cardiac Department, Carmichael Medical College Hospitals, Calcutta.

SHORTLY after my return in 1922 from the heart clinic of Sir Thomas Lewis at the University College Hospital, London, I commenced a study of heart diseases as met with in Calcutta. My observations were largely made on private patients at their homes, with the obvious advantage of following these cases up for over two years. In all cases Lewis' method of working up and recording them was followed, and polygraphic tracings were taken whenever required. Unfortunately, however, it was not always possible to record the daily output of urine, the hours of sleep, and other details as accurately as they would be done in a hospital. Nevertheless, many striking facts were brought to light, and some of these relate especially to the behaviour of digitalis in cases of heart failure. Since some of these results are at variance with those obtained by Mackenzie, Lewis and others, special care was taken to ensure accuracy. To facilitate a better understanding of these problems, it has been found necessary to discuss some points before mentioning the procedure that was followed.

Choice of Preparation.—The B. P. preparations in common use are the tincture, infusion and pulvis digitalis. So far, we have not isolated any single pure glucoside which may be regarded as the essentially active principle.

The tendency therefore is to administer the whole drug, including as many glucosides, etc., as possible. Recent experiences in America and Germany have favoured the use of the powdered leaf, and it is claimed that this gives the most certain and favourable results, but there are numerous practical objections to the routine use of the powdered digitalis leaf in India. To be physiologically active, several conditions must be fulfilled:—

- (1) The folia must have been of the second year; (2) collected at the proper season; (3) dried for some hours at 60° C. to destroy the ferments, otherwise the glucosides will be rapidly destroyed; (4) kept dry, free from dust, heat and strong light; (5) not touched with moist hands, otherwise they will be overgrown with fungi; and (6) lastly, an alcoholic tincture made

from these folia should be biologically assayed to prove the potency of the leaf.

It is futile to expect that every sample of powdered leaf has satisfied all these conditions. Bad leaf, badly stored, when pulverised, would possibly be "Pulv. digitalis with fungi without glucosides." To sum up, therefore, pulv. digitalis as served up by local chemists in the *mofussil* is a preparation regarding which (1) one does not know whether it was ever physiologically active, and (2) whether such activity has been retained on storage.

With regard to infusion of digitalis much greater uncertainty prevails. The physician is probably asking for the freshly made infusion, but in most cases the druggist opens a stocked liquid drug which is imported and labelled as "Infusion of digitalis, concentrated." The druggist dilutes this to 1 in 8 and serves it out as the B. P. infusion of digitalis. Many druggists have confessed that this is their usual practice. What life-saving property will this miserable old infusion be likely to possess? Assuming that the infusion is freshly made, the leaf has not been standardised, and may be defective. Further, the leaves are usually infused for a few moments only, and very little of the active constituents are diffused into the water. The best infusion is obtained by following the directions of the U. S. pharmacopœia, where it must stand for one hour, and a little alcohol is added before straining. With all conditions properly fulfilled, the longest period that an active infusion can last is one week.

Lastly we arrive at the tincture. The reasons for preferring the standardised tincture are numerous and weighty. We have favourable reports by most cardiologists on the tincture. Further, each specimen, before being bottled, is chemically and biologically tested in terms of "heart tonic units." Most of our cases of heart failure are *in extremis* and require an active preparation which is readily absorbed. The standardised alcoholic tincture fulfils these requirements. But there is one serious and unavoidable defect in the tincture, viz., its gradual deterioration with age and great loss of potency. In these clinical studies, this aspect of deterioration and loss of potency has been studied. This fact must be clearly remembered, otherwise valuable lives may be lost. There is only one immediate remedy for this defect, a remedy in the hands of all practitioners, and it lies in the use of massive doses of the best tincture, heedless of the posological tables and the alarm of the druggist. Through the courtesy and with the help of Major R. N. Chopra, I.M.S., and Capt. P. De. (T.C.), experimental studies with various samples of the tincture as actually used on patients have been made, and these results have been reported elsewhere in the March number of this journal.

Having chosen the standardised tincture, it was found that the best results were obtained by procuring an original 4-ounce bottle direct from

the agents, with instructions to supply from the latest consignment.

This bottle was kept in a cool, dark place, each dose was accurately measured out, and the bottle was at once tightly corked. This dose of tincture was diluted with water and taken at once on an empty stomach. In practically all these cases this method of administering digitalis was followed.

In passing, mention might be made of the use of Native's digitalin granules in two cases of heart failure complicating uræmia, which had failed to respond to the tinctures of digitalis and strophanthus. Both these cases did badly and died. In two other cases rectal administration of the tincture diluted with normal saline was beneficial. In no case was digitalin injected, since Mackenzie states it to be useless, but several desperately grave cases received instead an initial injection of Merck's G. strophanthin, gr. 1/200 intravenously with immediate and striking benefit.

Dosage.—With regard to dosage, digitalis stands apart from other drugs as being unique. With our present-day knowledge of the mode of action of digitalis in heart failure, for all practical purposes it is quite useless to mark the dose as 5 to 15 minims. In fact this officially prescribed dosage is a fruitful source of unwarranted caution and alarm on the part of the physician. Let us at the outset understand the essential principles concerned. The dose of any drug should be adjusted only according to its therapeutic utility. Digitalis can fulfil its purpose only when a certain large quantity has been given and has accumulated in the system in a certain period. Other active drugs such as belladonna, opium or *Cannabis indica* usually exert their respective therapeutic effects with 2 or 3 full doses according to the B. P. Thus with these drugs the therapeutic dose is nearly equal to the maximum B. P. dose. Digitalis, however, behaves quite differently. Though the maximum B. P. dose is 15 minims, one does not get any therapeutic effect unless a total dose of about half an ounce of the standardised tincture is taken. That is to say, it takes at least 240 minims, or 16 times the maximum B. P. dose before therapeutic effects are obtained. This is the finding of British and American workers. From this it follows that it is futile to remember and administer the B. P. dose of 10 or 15 minims when faced with a dying case. Cary Eggleston was the first to calculate the total dose of digitalis required on the basis of the weight and musculature of the patient. The more muscular the man, the heavier is his heart, and thus he would require a great deal more digitalis for therapeutic effects. It has been ascertained by Eggleston that 15 c.c., or 4½ fluid drachms of the standardised tincture, is required to "digitalise" a man weighing 100 lbs. Taking this as the average total dose required, the rational way of prescribing should be to

divide this up into a few big doses, according to the urgency of the case. In moribund patients with heart disease, the safe initial dose should be $1\frac{1}{2}$ or even 2 fluid drachms. This should be followed up by smaller doses of $\frac{1}{2}$ drachm every 4 or 6 hours, until the total required dose of 4 to 6 drachms has gone in. This method of "rapid digitalisation" results in equally rapid relief of distress and is not in any way dangerous.

While this rapid method may be a method of choice in Europe and America, one feels convinced, after a careful study in Calcutta of over 150 cases of heart failure, that it is the only method left to us when faced with a dying case and feebly armed with a weak, though standardised tincture of digitalis. In such cases one has often holdly administered a daily dose of 2 to 3 drachms for a couple of days with immediate relief. Children of from 6 to 12 years old stand proportionately big doses extremely well.

Indications in Chronic Heart Disease.—Until recently it was the general practice to administer digitalis indiscriminately. The hearing of a bruit anywhere over the præcordium conjured up the memory of digitalis. Fortunately, with the advent of newer knowledge, precise indications were laid down. The cardinal indication for the use of digitalis may be summed up in two words, *heart failure*. Obviously, the earlier the stage in which treatment is begun, the better it works. Heart failure includes a group of distressing symptoms, such as dyspnoea, cough, præcordial pain, and extreme exhaustion. The physical signs of venous congestion and other sequelæ usually appear later than the symptoms, and must therefore be regarded as late events. The earliest stage of failure, which is totally devoid of gross physical signs, must be correctly diagnosed. Diagnosis is rendered easy by a comparison with the patient's previous exercise tolerance, and by the presence of cardiac enlargement, with or without valvular disease. In the presence of these factors, we should regard these symptoms of distress as early evidences of heart failure.

Recently, however, the tendency is to give digitalis and also try to discover the root cause underlying heart failure. There are two conditions which precipitate the onset of heart failure. Firstly, the presence of a grave though obscure infection in some part of the body; and secondly, the onset of an abnormal rhythm with tachycardia, as in auricular fibrillation. The infective cause is by far the commonest, and therefore prompt attention to this root cause often succeeds admirably. But this alone does not suffice, and one has been compelled to advise such patients to invest in a bottle of standardised tincture of digitalis for the first few weeks. This dual measure improves the progress of the case, after which the patient can afford to do without digitalis. In the second group of cases,

with heart failure there is abnormal rhythm with tachycardia, as in auricular fibrillation.

Both Mackenzie and Lewis emphatically state that auricular fibrillation with ventricular tachycardia constitute the cardinal indication for the use of digitalis. Lewis writes, "The giving of digitalis to unselected heart cases is much to be deplored. Those who regard digitalis as a cardiac stimulant mistake its character; its chief action is to rest the heart. To the heart, fox-glove is not tonic but powerfully hypnotic. It controls the diastole of the heart; it extends the period of ventricular sleep." According to Lewis, there is no direct proof that digitalis is beneficial in cases of heart failure, except in those associated with auricular fibrillation. It is his conviction that digitalis owes its therapeutic success essentially to its power of blocking the passage of impulses from the auricle to the ventricle. By doing this in a case of auricular fibrillation with high ventricular rates, it gives the ventricles rest. This rest revives them, and thus they work efficiently.

With this view, however, many British and American physicians disagree. They maintain that though in all other cases the benefit derived from digitalis is not as definite and dramatic as in cases with auricular fibrillation, still a good proportion of cases with heart failure with normal rhythm improve with digitalis. The present study of a series of over 150 cases of heart failure in Calcutta has revealed some instructive points. The most striking finding in Calcutta is the extremely low percentage of cases of auricular fibrillation. The statistics of the different heart clinics in Europe and America tell us that in about 66 per cent. of all cases of heart failure there is auricular fibrillation, with or without tachycardia. But in the present series of 150 cases, only 9 cases had auricular fibrillation, or only 6 per cent. This extremely low incidence of auricular fibrillation among the cases of heart failure raises a difficulty in their treatment. Those who belong to Lewis' school would not use digitalis in these 94 per cent. of cases. Personally, I did not use digitalis in the beginning, but the results were disappointing.

Absolute rest in bed, proper diet, sleep and elimination did not cause improvement, therefore digitalis therapy was added, often with conspicuous benefit.

To sum up, the presence of definite symptoms or signs pointing to heart failure fully justifies the free, and often extravagant use of digitalis. Whether there is auricular fibrillation or a normal physiological rhythm or a normal heart rate does not matter. With this measure, however, any associated infection present anywhere in the body must be radically treated, otherwise results will be disappointing. It is not an exaggeration to state that the profession has not paid sufficient heed to these "focal infections," which drag over

90 per cent. of our heart failure cases down to the grave.

Contra-indications.—While limiting ourselves to cases of heart failure in the course of chronic heart disease only, very few contra-indications really exist. Text books mention that digitalis must not be used in cases of paroxysmal auricular fibrillation and in partial heart-block. Both these conditions may be regarded as clinical curiosities in the cases which we meet with in this country, the incidence of either of these being less than 2 per cent. By studying facts and ignoring catch phrases one can conclude that—provided heart failure is definitely present—there is hardly any contra-indication to digitalis worth consideration. Some doubt exists with regard to the procedure to adopt in cases of complete heart block, which have numbered as much as 5 per cent. in this series. Two of these cases have alternately reverted to normal rhythm quite suddenly and subsequently relapsed. Such cases have complete auricular-ventricular bundle-block only as a transient phenomenon. In these rare cases, therefore, digitalis can do harm by converting this temporary block into a permanent one. Once a case has developed by itself into permanent and complete auricular-ventricular block, no further mischief can be caused by digitalis. On the other hand, one has found digitalis therapy in two cases of complete heart block to be followed by a slight increase in the ventricular rate with a better exercise tolerance in the patient. Advanced pregnancy is no contra-indication, and a good many patients with grave heart failure complicating pregnancy have been safely tided over the crisis by bold digitalis medication.

Clinical Results.—In the course of these studies several difficulties were met with. These difficulties serve to illustrate two well-known but ill-remembered clinical truths. Firstly, one's clinical instinct and insight are often clouded by preconceived ideas; secondly, impressions based on a rough clinical study are often quite wrong and differ widely from the results arrived at by accurate and painstaking work.

Massive Dosage Required.—The question of dosage will be taken up first. All workers are agreed that it takes from 4 to 6 drachms of the standardised tincture to digitalise a case of heart failure. Further, Mackenzie states that digitalis has very little capacity to slow the tachycardia which starts in a normal manner at the sino-auricular node.

Therefore in this uncertain group of non-fibrillating cases not easily amenable to digitalis medication, one expected that it would take a bigger dose to make any impression. The group of heart failure cases that were first seen were treated as usual without any digitalis. Some of these did well, but the majority did not progress. Finally these were put on digitalis, more from scepticism and clinical curiosity than any conviction.

Usually, 15 to 20 minims of the standardised tincture was prescribed, along with alkaline diuretics in a mixture three times a day. It was noted that most of these patients stuck to their bottle regularly for months without the least sign of cumulation, and with varying benefit. At first, this fact seemed a little surprising, but the surprise was countered by two considerations:—(1) These cases, not being 'auricular fibrillators,' would consume relatively more digitalis, and (2) digitalis mixed with other drugs would lose its potency *after* being made up by the chemists. Thus, in spite of all these doubts, one still believed and taught in the wards that in this country it takes 4 to 6 drachms of the standardised tincture to bring on digitalis cumulation as in Europe and America. One never bothered even to add up the daily doses to find out the actual quantity required. At last, in August 1923, a European patient came for treatment for cardiac debility. Auricular fibrillation was present with a ventricular tachycardia of 140. It was decided to slow down this tachycardia rapidly by digitalis and then to put him on to quinidine. To get the quickest and most certain results, the patient was given an original 4-ounce bottle of the tincture direct from the manufacturers, with instructions to take 20 minims four times a day. With a daily dose of 80 minims one confidently predicted that by the 5th or 6th day his heart rate would be down to 80 per minute, the result of a total dose of 7 or 8 drachms. Contrary to expectation, however, the heart rate was still 120, and there was not the least sign of any intolerance. This patient eventually consumed 18 drachms in 13 days and had an intravenous injection of strophanthin before the rate fell to 80. Every case subsequent to this has been carefully dosed with digitalis, and one has not yet seen digitalis poison a single case of heart failure with a total dose of 4 or 5 drachms. In all the 9 cases of auricular fibrillation with tachycardia studied, the minimal total dose to produce minor toxic symptoms was 10 drachms and the highest was 21 drachms. Next, taking the big series (94 per cent.) of cases of myocardial degeneration with or without valvular disease, where there was heart failure with normal cardiac mechanism it was found that the smallest dose which produced minor toxic effects was 9 drachms, and the highest dose was 29 drachms in 26 days. One can recall 10 clear cases where a whole 4-ounce bottle of the tincture has been consumed within a month. Some of these have greatly benefited, but none of these 10 cases shewed toxic symptoms. This fact seems startling when Robinson cautions against the free use of digitalis in myocardial cases and writes, "the heart is often unusually susceptible to digitalis in the class of cases under consideration, and toxic effects may be produced by relatively small doses."

The massive doses have been worked out by carefully adding up the daily dose, whereas most of us had the impression that 4 to 6 drachms

alone would suffice in all cases. Several colleagues who have made their own observations recently, have also arrived at the same result. Some of them maintain that decided improvement in the patient's condition has not commenced before the 9th drachm or the limit of digitalis tolerance has been reached. But this is not the point in dispute. Clinically, improvement may commence with the first dose of digitalis or without any digitalis, where it is certainly due to other factors and not to the digitalis. Ordinarily one would expect a suitable case in cold countries to shew early toxic symptoms after 4 to 6 drachms of the tincture, but in this country it takes a minimum of 9 drachms to get the same toxic effects. This discussion as regards dosage is not merely academic. Ordinarily, practitioners have a feeling that the minimum dose of the B. P. is the optimum dose for an Indian. Even today there are many who stick to their 5 minim doses thrice daily. A week or ten days' trial is given; nothing happens, and the patient is regarded as incurable. If we remember that digitalis begins to act only after a good deal of it has been stored up in the body, we should not hesitate to start with massive doses in an endeavour to store it up quickly in the body. On an average, the human system can destroy about 22 minims of the tincture a day. Therefore, unless the initial daily dose was three or four times this quantity, there would not be much storing up of digitalis.

So far, it has not been possible to find out definitely which type or group of heart failure case requires the most massive dosage. On the whole it appears that the strongly built, heavy, middle-aged man invariably tolerates a bigger total dose than 10 drachms. Also the greater the initial hepatic enlargement and the deeper the icteric tinge present, the bigger the dose of digitalis that will be required. These no doubt are very rough guides, but this is as far as one's observations entitle one to state. Two illustrations from actual experience will perhaps convince the practitioner of the grave dangers attending the practice of giving too little digitalis.

The first case was a European male, aged 41, said to be suffering from severe dyspnoea, cough, palpitation and precordial pain for six months. This case was variously diagnosed and treated as bronchial asthma, renal asthma, etc., with no benefit. The next diagnosis made was cardiac asthma, for which plenty of camphor, caffeine and strychnine were prescribed, but only 10 minims of tincture of digitalis a day, and the patient was given up as quite hopeless. Ultimately the patient came under the writer's observation, when auricular fibrillation with grossly irregular ventricular tachycardia of 160 was discovered for the first time. The only drug prescribed was the standardised tincture of digitalis, besides an intravenous strophanthin (gr. 1/200) for its immediate effect. As the effect of the intravenous strophanthin passes off in 24 hours, digitalis was pushed with all haste. In such a grave case, one could have used half an ounce of tincture of digitalis as the initial dose, with perfect safety and with almost immediate results. Single big doses of 2 drachms have been recently tried in America and definite beneficial effects obtained in 24 hours. However, in the case in point,

2 drachm doses were given per diem. After one ounce had been taken in 4 days, the heart rate fell only to 120. It reached 84 only after 20 drachms had been taken in 12 days. In such a grave type of case, most commonly seen here, if one were not armed with Merck's strophanthin, and merely used 10 minims of tincture of digitalis thrice daily, the patient would have been dead long before digitalis had got a grip on his auricular-ventricular bundle. Knowing that digitalis is the sheet anchor in heart failure with auricular fibrillation, one completely ignored the posological tables and toxicological notes. The heart must be slowed down, and digitalis is our only weapon if used quite fearlessly.

A second case illustrating the danger of too little digitalis occurred in a Hindu female aged 22, with advanced heart failure and mitral stenosis, complicating 8 months' pregnancy. She had the same massive doses, and when her heart rate fell to 88 she had a premature labour, with very severe post-partum hæmorrhage. The child died shortly after birth, but the mother eventually walked out of hospital, apparently quite fit.

Looking back to the period spent in Sir Thomas Lewis' heart clinic, with several hundreds of heart cases passing through every month, one found really very few cases who first asked for treatment when too far gone. Most of those cases were in the early stages of heart failure. It was only rarely that intravenous strophanthin was found necessary; on the contrary it was interesting to observe that many of these heart failure cases got no drug at all for the first week to enable us to follow the therapeutic effects of physical and mental rest. Contrast with this the 20 per cent. of heart failure cases in Calcutta who received a full dose (gr. 1/125) of intravenous strophanthin before they could be trusted to survive the night. Obviously these 20 per cent. of cases required massive doses of digitalis by the mouth.

Another fact which one has noticed is the extremely good tolerance shewn by some children to proportionately big doses. A child of four with mitral stenosis, a dilated and failing heart, had a heart rate of 160 per minute. This child metabolised, as it were, 20 minims a day for one month, but the rate fell to 120 and no toxic symptoms occurred. Children from 6 to 8 years old have been successfully digitalised with an average total dose of 4 to 6 drachms in 12 days' time. In other words, a child of 8 in this country stands the same quantity of the tincture as a full-grown adult in Europe or America. Young persons from 12 to 15 years old can tolerate nearly the same massive doses as an adult. Mackenzie states that once a case of auricular fibrillation is fully under digitalis effect, it requires a very small dose of from 5 to 10 minims a day to keep the heart rate constant. On the contrary, all the cases of auricular fibrillation here have needed an average dose of 30 minims a day regularly for months to keep the rate at 80 to 90. Seeing that it takes anything from 2 to 4 times as much digitalis in this country to produce the same beneficial results on patients, both European and Indian as in England, we endeavoured to find an explanation for this remarkable discrepancy. A large series of heart failure cases

was treated with standardised tincture of digitalis bought direct from the manufacturers in original sealed 4-ounce bottles. It was noted how much was required to induce one or other of the cumulative effects. Each sample that was clinically tested on diseased persons was experimentally tested with a view to finding out exactly how deficient it was in the active principles. This comparative study of a large number of samples has yielded interesting results, which have been published in the March 1925 issue of this journal. While all these samples of tincture purchased and used in this country proved to be much weaker than the standard tincture as used in Europe and America, it seems also probable that some part of the ingested tincture is decomposed either in the alimentary tract or in the liver, and therefore does not reach the general circulation. Clinically it was found that those with the worst hepatic derangement consequent on passive congestion often needed and tolerated relatively more digitalis than others, and it is not unlikely that delay in absorption from the alimentary tract combined with further delay in the liver would determine the increased breaking down of some of the active principles.

Benefit.—(i) *Age.*—In estimating the benefit which may be expected from digitalis, the initial condition of the myocardium counts for a great deal. If the myocardium is relatively sound, as in younger persons, more benefit, both in degree and in duration, may be expected. All things being equal, the younger the age, the less grave the issue when digitalis has to be used.

(ii) The heart is normally smaller in women by nearly 2 ounces than in men. The myocardial efficiency may be said to be less, proportionately. Apart from this, it is difficult to state which sex is likely to do better. The imperative necessity of man to work for his living, though incapacitated, often nullifies all good results. Similarly the strain of repeated pregnancies and lactation proves equally disastrous in woman.

(iii) *Occupation.*—It is usually believed that the hard-working man fares the worst with heart disease, while the sedentary worker keeps better, once he has improved with treatment. This, however, is not strictly in accordance with one's own results. The man who is used to physical exertion has built up in the past a much stronger myocardium. Provided this type of patient cuts down his future work, he has a longer expectation of life before him than the person who has always been a clerk.

(iv) *Type of Disease.*—Chronic heart disease has three common causes: (a) the rheumatic group (10 to 30 years old); (b) the syphilitic group (30 to 50 years old); (c) the senile sclerosis group (45 years and onwards). Besides these, two minor groups may be added, (d) the hypertensive group, and (e) pregnancy with grave anæmia.

(a) *The rheumatic group.*—Digitalis most readily benefits the rheumatic group because the

heart muscle has a very good blood supply through fairly healthy coronary vessels. The presence of both aortic and mitral valvular damage makes the issue more unfavourable.

(b) *The syphilitic group.*—There is still considerable dispute regarding the behaviour of a syphilitic myocardium under digitalis.

There are several complicating factors such as the age of the patient, duration of infection, the stage of heart disease at which treatment is begun, past anti-luetic treatment, valvular disease as a complication, and syphilitic coronary sclerosis. It is therefore extremely difficult to conclude anything definitely. The heart cases in which digitalis is used here are cases of advanced cardiac failure. When such a grave case has also a strongly positive Wassermann reaction, one has not found it to survive more than 18 months, in spite of digitalis and full anti-syphilitic measures. By far the worst outlook is to be expected when the triad is present of advanced failure, free aortic regurgitation and active syphilis with a strongly positive Wassermann reaction. No case with this triad fully developed has survived longer than 12 months. The presence of aortic regurgitation adds a tremendous risk to the already failing syphilitic heart.

(c) *The senile sclerotic group.*—On a priori grounds one would expect an aged heart to fare the worst with digitalis. At one time it was taught that digitalis is dangerous to the senile heart. It was believed that a senile heart may have fatty changes, and may suddenly rupture with digitalis. This is no longer true. The fact is that digitalis most favourably effects a senile heart in failure. Quite a large number of these old patients are alive to-day whose heart failed badly two years ago. On further analysing the possible causes of this favourable result in these few cases one found that the arteries were not too rigid, the blood pressure was not too high, and the kidneys were functioning fairly well. To sum up, one can conclude that digitalis is most beneficial for a senile heart for many years, provided the "tubing" is not rotten, and the "filters" not choked.

(d) *The hypertensive group.*—Apart from these three main types of heart disease, there is another common type which may be named the hypertensive type. This type is often seen in middle aged men and women, with very high arterial blood pressure and urinary findings typical of interstitial nephritis. The later clinical features are partly due to heart failure and partly to uræmia. Professor Chauffard of Paris in his clinical lectures emphasised the utility of combining digitalis therapy along with eliminatory measures. Following his ideas, one gave to these cases large doses of the standardised tincture. With defective kidneys, one would expect small doses to be retained longer in the system and to do good. But the reverse was found to be the

case. Two of these cases with regular tachycardia of 140 and pulsus alternans consumed 3 ounces of tincture of digitalis a month for three months without any toxic effect on the heart, kidneys or bowels. This type of case is notorious for the sudden high fluctuations of blood pressure, and was carefully studied from this stand-point. Digitalis did not tend to raise the blood pressure; on the contrary a conspicuous fall was noted, possibly due to other measures.

(c) *Pregnancy with grave anæmia.*—This type looms large, and is responsible for many deaths. The patient is extremely pale, water-logged, weak, dyspnoic and almost pulseless. The picture towards the end is typically one of grave heart failure. Treatment is directed towards supporting the circulation and filling her up with as much "whole blood" as can be got from a suitable donor. Intravenous strophanthin, followed by digitalis orally, alters the picture of the case for a time, but unless rapid blood-regeneration can be stimulated and all blood-destruction effectively stopped, no permanent good can result. In hospital practice, malaria, ankylostomiasis and *B. coli* pyelitis have been found in many cases to have caused the anæmia; but in other cases no such cause has been discovered. The unfortunate feature of such cases is that when the patient has just rallied from heart failure, premature labour comes on and carries the patient off. This has repeatedly occurred. One lucky patient just survived abortion and eventually walked out of hospital. Two post-mortems were obtained and section of the heart muscle revealed an intense and diffuse fatty degeneration of the heart muscle. With such grave anæmias, digitalis is of conspicuous benefit for a time.

Digitalis Cumulation.—Digitalis cumulation is an event of which a great deal is written in books, but little is directly heard of from colleagues, and which is only rarely seen in this country by the general practitioner. Nevertheless, there is always a genuine fear in the minds of all. The fact remains that the potency of all samples of tincture of digitalis that has reached us is extremely feeble, and thus it is well nigh impossible to see a single case of digitalis cumulation when prescribed in 10 to 15 minim doses. The body can destroy 22 minims of the ideally potent tincture a day, and certainly more than 30 minims of the tincture as it reaches a hot country. Unless a patient regularly took one drachm for many weeks, he could not possibly accumulate sufficient to give rise to toxic effects.

The best results and greatest benefit to the patient can only be achieved by following MacKenzie's plan, which consists in starting the treatment with big doses, and keeping it up for 4 to 7 days, or until minor toxic effects are produced. It is worthy of note that the stage of optimum benefit to the patient is very close to the stage of minor intoxication. It behoves one, therefore, to strive in all cases to just reach the state of

minor toxic effects. These may be grouped thus:—

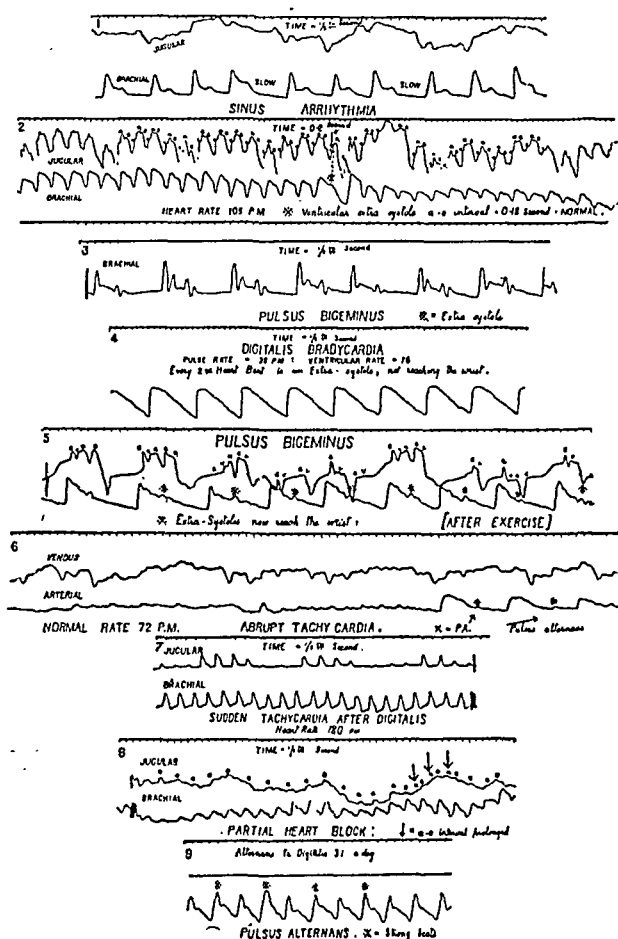

(1) *Heart.*—The most conspicuous effect is definite slowing to 80 or less. The slowing may be either quite regular and uniform (rare), or irregular, which is more common. The commonest type of irregularity is due to occasional premature beats, followed by a long pause. A rare type of irregularity has been caused by sinus arrhythmia, which is an expression of increase in vagal tone. There is quickening of the rate during inspiration and slowing during expiration. Another type of irregularity is known as coupling of the beats or "pulsus bigeminus." Directly this stage is reached, one must be cautious. Pulsus bigeminus means that every alternate beat is replaced regularly by a weak premature contraction, followed by a long pause. More dangerous than this stage is one which I have named "digitalis bradycardia." This stage was met with in 4 cases who did not obey instructions to stop digitalis. One of these patients had severe palpitation after excessive digitalis. On examining him the pulse was slow and regular at 38 per minute. On auscultation the ventricular rate was the same, 38 p.m., and no heart sounds were heard during these long pauses. Slight exercise, however, altered the picture. At the early part of each long pause was heard a faint single sound, caused by a weak premature beat which could not open the aortic valves. The pulse rate still remained 38 while the heart rate was exactly its double, 76 p.m. This rare and dangerous stage of bradycardia is easily mistaken for complete heart block, but is really an extreme condition where the premature contraction is too feeble to produce even a sound. A fourth rare condition resulting from digitalis cumulation is the occurrence of brief paroxysms of tachycardia, alternating with bradycardia. For instance, 10 slow regular beats at 50 p.m. are followed by 18 or 20 quick beats at 140 per minute. These are nothing but multiple extra-systoles, all grouped together. Another rare clinical condition after digitalis is partial heart block. In the 94 per cent. of our cases of heart failure with normal rhythm, digitalis induced a slowing of the whole heart, starting from the sino-auricular node. Electro-cardiographic tracings reveal a delayed conduction time from auricles to ventricles, but very rarely are auricular impulses held back by the auricular-ventricular bundle. Clinically one very rarely sees a digitalis slowing caused by partial heart block. Another type of slowing is quite regular and is associated with alternate strong and weak beats, called pulsus alternans. This is a digitalis effect and disappears when the drug is withheld. Complete heart block and auricular fibrillation have not been met with as caused by digitalis. While slowing of the heart is so well known, digitalis tachycardia is rarely seen. In three cases which were having big doses of digitalis, the heart rate had fallen to about 88. The next day regular tachycardia of 180 p.m. was seen, and the patient was in distress. Calomel and magnesium sulphate were given at once, because the patient had a coated tongue and constipation. Digitalis was stopped for a day. Tachycardia stopped suddenly, the heart rate was 95. More digitalis was added until the other typical toxic effects were produced. This sudden paroxysmal tachycardia has been regarded by some as an irritant effect of digitalis on the heart muscle. But this is not proved. A patient with digitalis tachycardia as a toxic symptom should also have nausea, vomiting, etc., and should not tolerate any further addition of digitalis. These three cases were not typical as regards the other features of toxicity. This tachycardia may therefore be due partly to excess of digitalis in the heart and partly to intestinal auto-intoxication.

(2) *Gastro-Intestinal Tract.*—Sudden and severe anorexia is almost the first symptom of digitalis intolerance. Following this are nausea and vomiting. Excessive purging is rare with digitalis, but specially frequent when too much strophanthus is taken.

(3) *Kidneys*.—Diminished secretion of urine is a common sign, and is evident when the daily output is being measured.

(4) *Weakness and Prostration*.—A patient who is improving with full doses also feels stronger and more fit. If the minor toxic effects are ignored, then he loses ground rapidly and feels extremely weak and helpless. The physician's dread of digitalis cumulation is so great that digitalis is stopped if any patient who has had it gets a little diarrhoea. Diarrhoea never occurs singly as a digitalis effect, but is always preceded by nausea, vomiting and the typical digitalis pulse.

CHART I.

Types of Digitalis Pulse.

1. Sinus arrhythmia, with quickening on inspiration and slowing on expiration.
2. * = Premature beat of ventricular origin, followed by a compensatory pause.
3. Pulsus bigeminus, or coupled beats: here an extra-systole replaces every alternate beat.
4. Digitalis bradycardia, where the alternate extra-systole does not reach the wrist. Pulse rate is only 38 p.m., but the ventricular rate is 76 p.m.
5. Same case as Fig. 4, but after exercise. Extra-systoles are more powerful and now reach the wrist. Pulse rate = 76 p.m.
6. Rare type: normal rate is abruptly followed by tachycardia of 160 p.m., and finally by pulsus alternans.
* = alternate weak beat.
7. Rare type: sudden paroxysmal tachycardia of 180 after digitalis: called "digitalis tachycardia."
8. Partial heart block: ψ = a-c. interval longer than 0.2 second.
9. Pulsus alternans after digitalis.
* = strong beats.

This is a summary of the results obtained after a study of only 150 cases. The salient points may be summarised thus:—

Summary and Conclusions.

1. Over 150 cases of heart failure have been clinically studied, of which a large number were in imminent danger.
2. Of these only 6 per cent. of cases had auricular fibrillation, while 94 per cent. had normal rhythm starting at the sino-auricular node. On the contrary, over 66 per cent. of all cases of heart failure in Europe and America have auricular fibrillation.
3. Standardised tinctures obtained direct from Messrs. Parke Davis & Co. were used in almost all the cases, in preference to other preparations of digitalis.
4. The average quantity of tincture necessary to induce toxic effects varies in cold countries from 4 to 7 fluid drachms. In Calcutta the smallest dose required was 9 drachms, the highest was 29 drachms, and the average dose was well over 14 drachms. This result is partly due to loss of potency of tincture and partly to increased decomposition in the alimentary tract and liver.
5. To obtain prompt results in grave cases, the tincture has been used and ought to be used in doses of 2 to 3 drachms per day for 5 days.
6. Cases of failure with normal rhythm require nearly the same high dosage as cases with auricular fibrillation.
7. Cases of failure, with free aortic regurgitation, syphilitic myocarditis and a strongly positive Wassermann reaction, do not benefit permanently from digitalis.
8. Senile hearts, cases of marked hypertension and cases of grave anaemia with fatty degeneration of the myocardium respond exceedingly well to digitalis.
9. The stage of optimum benefit from digitalis usually merges into the stage of minor intoxication from cumulation of the drug.
10. With the tincture as obtained in this country it is extremely rare to get toxic effects from the use of tincture digitalis in B. P. doses of 15 minims thrice daily.
11. The toxic effects, such as slowing of the heart rate, nausea, vomiting and diminished diuresis often come on almost simultaneously, and after massive doses of 2 drachms a day have been taken for more than 7 days.
12. Apart from slowing, digitalis may rarely provoke a sudden paroxysmal tachycardia of 180 p.m., termed "digitalis tachycardia."

THE TREATMENT OF CHOLERA BY CRESOL AND ACID.

By F. J. PALMER,

LIEUT.-COL., R.A.M.C. (retd.),

Binnakandy P. O., Silchar, Cachar.

IN the *Indian Medical Gazette* for August 1924 there was published a paper by the writer on the treatment of cholera by cresol.

As the result of experience, the treatment therein outlined had been modified in one respect before publication had actually occurred.

On theoretical grounds one would be inclined to agree with Rogers in his opinion that acidæmia plays a considerable part in the fatal issue in cholera. It is only reasonable to suppose that the acidity of the blood is considerably increased when, in the course of the disease, a large amount of alkaline fluid is poured into the bowel.

Rogers endeavoured to combat this by alkaline intravenous injections.

With the same end in view, for a time I gave alkaline water after the acute choleraic symptoms had subsided.

Though in my own hands this administration yielded very fair results, I was always somewhat apprehensive that, in the hands of inadequately trained personnel, the exhibition of alkalis might not always be unfraught with danger.

In two cases in out-gardens, in which the patients had at first appeared to do well, there was a suspicion that the set-back and subsequent fatal issue might have been due to the too early administration of alkali. It remained a suspicion, but, on this account, the administration of alkalis at any stage in the treatment was discontinued, without, apparently, any loss of efficiency.

At the same time it seemed increasingly evident that, at the beginning of cresol treatment, I had been inclined to stop administration of it too early. As I stated in the postscript to my former paper on the subject, cresol was then continued in diminishing doses till the third day.

During this stage in evolution my belief in the efficacy of dilute sulphuric acid as a prophylactic had been gradually strengthening, and I had often speculated as to how much of the good effects of Tomb's treatment was due to the acid that it contained.

The fear of increasing acidosis, however, had deterred me from putting the obvious application into practice. This fear must have been common to many, for even as a student one learns the susceptibility of the cholera vibrio to acid, and the use of this acid as a prophylactic is very common.

It was determined to try its effect, in association with cresol, in the treatment of cholera.

The following dosage was decided on, and instructions issued:—

1 to 3 years, cresol 1 m., acid sulph. aromat. 1 m., water 1 oz.

3 to 7 years, cresol 2 m., acid sulph. aromat. 2 m., water 2 ozs.

7 to 12 years, cresol 3 m., acid sulph. aromat. 3 m., water 3 ozs.

12 to 16 years, cresol 4 m., acid sulph. aromat. 4 m., water 4 ozs.

Adult, cresol 4 m., acid sulph. aromat. 5 m., water 4 ozs.

Acid sulph. dil. may be used instead of acid sulph. aromat., but is naturally lacking in the carminative properties of the latter.

I believe that dilute hydrochloric acid might prove equally useful.

It will be observed that the dose of acid is a small one, and graduated in view of the greater liability of children to acidosis.

The risk of this may possibly be exaggerated, as the flow in cholera is from the tissues to the interior of the bowel, but some absorption must occur or there would be no toxæmia.

The doses above given are administered as before; every quarter of an hour for the first eight doses, and every half hour for the next four doses. The acid is then omitted; and the cresol alone, in the same dose as before, continued at hourly intervals for another twelve doses, and thereafter at two-hourly intervals for another day. On the third day it is given at three-hourly intervals.

So far only nine cases have been treated by this method, all of them adults, but the results have been quite promising.

Eight of the cases were collapsed when first seen, and in three of these the collapse was absolute, no pulse being obtained even in the brachial artery.

There were two deaths in the series, there being only one death in the first seven cases. The severity of the cases suggests that this treatment is superior to that with cresol alone. This should be easily capable of proof or disproof during the coming hot weather.

This is my only excuse for bringing such a small series of cases to notice.

The doses should be freshly made up. After acid has been added to cresol solution some precipitation of globules gradually occurs, and might possibly impair the efficiency of the mixture.

I have considered the possibility of combining kaolin with this mixture, but have had no opportunity as yet. I would hazard the suggestion that some of the good effect of kaolin may be due to the fact that it stimulates a toxin-deadened intestinal musculature to drive it and the accompanying toxic fluid further down the bowel where absorption is less active.

In conclusion let me emphasise that any treatment of cholera should only be judged by the results given when the treatment has been in conscientious hands. Many cases pass through their most critical stage at night, and it is then that the treatment is most likely to be left in the hands of relatives who, however kindly, are tired themselves, and in addition have no idea of time. This, of course, only applies to cases treated in their villages or lines.

A NOTE ON THE OUTDOOR ORGANISATION OF THE ASANSOL MINES BOARD OF HEALTH.

By Dr. J. W. TOMB, O.B.E., M.D., D.P.H.,

Chief Medical Officer, Mines Board of Health, Asansol.

THE article by the editor in the *Indian Medical Gazette* for December 1924 on "Some Experiments for the Solution of the Rural Health Problem in India" makes it likely that an account of the outdoor organisation of the Asansol Mines Board of Health may not prove uninteresting at this juncture.

The Asansol Mines Board of Health, which is constituted under (Bengal) Act II of 1912, was brought into active existence by Government during the war in the early part of 1916 to prevent "the outbreak and spread of dangerous epidemic disease" in the Asansol Mining Settlement.

The Mining Settlement which is situated in the District of Burdwan comprises the greater part of the sub-division of Asansol, the most western sub-division of Bengal. It lies 110 to 140 miles west of Calcutta, on the main line of the E. I. Railway from Calcutta to Delhi, which runs through the Settlement in its longer axis.

Within the Settlement are included 200 collieries, 490 villages and the two municipalities of Asansol (population 21,727) and Raniganj (population 14,536), the total population of the Settlement, according to the census of 1921, being 329,353.

The chief epidemic diseases in the Settlement are cholera and small-pox, plague being unknown in epidemic form.

The unit of administration adopted in the Settlement is the circle of the Sanitary Assistant which is about 36 sq. miles in area. Experience in the Mining Settlement has, moreover shewn that the largest area which any rural Sanitary Assistant can effectively deal with does not exceed 50 sq. miles. The number of rural Sanitary Assistants employed by the Mines Board of Health is 13.

The duties of each Sanitary Assistant are:—

1. To collect the vital statistics of his circle from the village chowkidars at the weekly chowkidari parade held at the police thana.
2. To verify these occurrences during the week.
3. To submit a weekly report on the sanitary condition of the villages visited and inspected by him while verifying the returns of births and deaths received from the chowkidars at the police thana or while on other duty.
4. To receive reports of any outbreak of cholera, small-pox or plague and to take immediate steps for its suppression.
5. To vaccinate during the first year of life all children born in his circle and all other persons found unvaccinated or requiring re-vaccination.

6. To give lectures on elementary hygiene in the primary schools of his circle.

7. To make certain that the burning ghats in his circle are kept in proper order by the staff of *doms* maintained by the Board for that purpose.

We may now consider in detail how these duties are carried out.

All members of the outdoor staff of the Board are called upon to maintain bicycles, for the purchase of which they are lent money, free of interest, by the Board and receive monthly bicycle allowances of Rs. 10 each.

Each Sanitary Assistant, as noted above, attends the weekly chowkidari parade at the police thana of his circle, and there notes down the births and deaths of his circle as reported by the village chowkidars.

During the week he verifies these occurrences, ascertaining as far as possible the real cause of death, which, in the majority of cases, is attributed by the chowkidar to "fever." The true cause of death, however, on enquiry from the relatives or others can be generally ascertained, as malaria, pneumonia, cholera, small-pox, snake-bite, childbirth, accidents, etc., are all well known to intelligent villagers.

The Sanitary Assistant also makes enquiry in each village regarding any births and deaths that may not have been reported by the chowkidar. Experience has proved that practically all deaths are reported in the Mining Settlement—as can be verified by the numbers of bodies disposed of at the burning ghats. About 2 per cent. of births, however, remain unreported.

A permanent register of the corrected returns of births and deaths is kept by the Sanitary Assistant in his office. A copy of this is submitted weekly to the office of the Mines Board for record, and another copy is sent to the police thana for forwarding to the office of the Civil Surgeon of the district.

The Sanitary Assistant also submits weekly to the Chief Sanitary Officer, on a form provided for the purpose, a report on the sanitary condition of the villages visited by him during the week. The headings of the form are as follows:—

"Name of village. Date of visit. Object of visit. Whether or not any epidemic was found. Number vaccinated. Water supply (whether satisfactory or not). Condition of village burning ghat. General sanitary condition of village."

Each Sanitary Assistant, at the end of each year, submits to the Chief Sanitary Officer a list of the villages in his circle in the most urgent need of wells. This list after due enquiry and verification is sent in to the Asansol Local Board which frames its yearly programme of well-construction in the Mining Settlement on the recommendations of the Mines Board staff. The Vice-Chairman of the Mines Board is *ex-officio*

Chairman of the Local Board, and the Chief Sanitary Officer is a nominated member.

For the immediate reporting of cases of cholera and small-pox the chowkidars of each circle are provided with coloured postcards. On the red cards is printed the word for cholera in Bengali and on the green the word for small-pox, the name of the village as well as the name of the chowkidar being written in, in ink on each card, by the Sanitary Assistant at the time of distribution. This system of notification of epidemic disease by coloured postcards, which was first introduced by the writer in the Mining Settlement in the year 1917, has now been adopted in several areas in Bihar and Orissa and seems suitable for general adoption throughout India.

On receiving information of any case of cholera or small-pox in the village, the chowkidar at once starts off on foot to the office of the Sanitary Assistant of his circle, which in the Mining Settlement is in no instance more than 6 miles away. For each case thus notified the chowkidar receives a reward of one rupee. The amount of money required annually for this purpose is quite small as, when once a single case of epidemic disease is notified in any village, the Board's staff keep in constant touch with the village until the epidemic is suppressed. On reaching the office of the Sanitary Assistant, if the Assistant be present the chowkidar notifies him verbally of the outbreak, but if as is more often the case, the Assistant is out on his duties, he drops the epidemic notification card into a small glass-fronted card box provided for the purpose outside the Sanitary Assistant's office door. The object of having a glass front to the box is to make certain that the Sanitary Assistant on his arrival back at his office will not fail to notice that an epidemic notification card has been placed in the box during his absence. The box is also located at such a height as to be out of the reach of children.

On receiving the epidemic notification card the Sanitary Assistant immediately proceeds by bicycle to the village named thereon and seeks out the chowkidar whose name was written on the card, by whom he is at once directed to the infected house. In case of small-pox no attempt is made at the isolation of the patient, as this is impracticable in rural health work in India, reliance being placed wholly on wholesale vaccination and re-vaccination, a procedure which experience has proved to be eminently satisfactory. It is also the duty of the Sanitary Assistant to report such cases at once to the Sanitary Inspector of his circle and to the office of the Mines Board of Health, on the form provided for the purpose, which in addition to "Name," "Age," "Sex," "Caste," has the following headings:—
 "Date of Onset of Fever; Date of Outbreak of Eruption; Date of Notification of Case by Chowkidar; Date of Previous Protection (if any)."

The date of outbreak of eruption, as pointed out by me elsewhere (*Lancet*, 1923, p. 485), furnishes a ready method of distinguishing small-pox from chicken-pox, since in chicken-pox the eruption always appears within 24 hours of the onset of fever (sometimes even appearing before the fever), whereas in small-pox there is always a well defined interval of at least 48 hours.

When the case is one of cholera, if the patient be not already under medical treatment, he is given eight doses of the essential oils' cholera mixture (vide *Indian Medical Gazette*, June 1923 and May 1924), by the Sanitary Assistant at half-hourly intervals. One prophylactic dose of this mixture is also administered daily to each inmate of the infected house until the patient is clinically recovered, the member or members of the family actually engaged in nursing the patient receiving two doses daily—night and morning. As recorded by me in the *Indian Medical Gazette* of May 1924, since this procedure was adopted three years ago no second case of cholera has occurred in any house in the Mining Settlement. Enquiry is then made as to the probable cause of the outbreak whether sporadic, epidemic or imported, and whether or not any tank in the village has been contaminated by washing the soiled clothes of the patient in it. Where the latter has occurred the tank is immediately sterilised and kept continuously sterilised with chloride of lime and also placed under guards at the expense of the Board to prevent the further use of the water until the epidemic is over. Sometimes where the tank is closely surrounded by dwelling houses and there is great likelihood that the water may be used in spite of the precautions enumerated above, the tank is also oiled with kerosene to render the water undrinkable. During the epidemic cholera season of the year (March to June) suitable tanks, with the consent of the owners, are reserved in each village by the Board for drinking purposes only and others for bathing purposes only. Formerly as a prophylactic measure it was customary to leave some coal-tar disinfectant, such as izal or cyllin, for the inmates of the infected houses to disinfect their hands with before eating; but this has been found unnecessary since the introduction of the essential oils cholera prophylactic.

As in the case of small-pox, the Sanitary Assistant immediately reports each case of cholera both to the Sanitary Inspector of his circle and to the office of the Mines Board of Health on a special form, which in the case of cholera includes the following headings:—

"Date of Notification of Case by Chowkidar; Date and Hour of Attack; Date and Hour of Arrival of Sanitary Assistant; Whether Case was found Collapsed or not; Treatment; Result."

With regard to vaccination, each Sanitary Assistant is provided with a bound register;

which the births of all children in his circle are recorded week by week and village by village. This register is regularly inspected by the Sanitary Inspector of the circle to see that it is kept posted up to date, and it is the duty of the Sanitary Assistant successfully to vaccinate each child whose name is there entered before it is one year old, unless it has in the meantime died or left the Mining Settlement. As there is a prejudice in Bengal against the vaccination of infants under six months old, no attempt is made in the Mining Settlement to vaccinate them under that age. This register incidentally affords a valuable check on the accuracy of the reports of vital occurrences by the village chowkidars, as it is found from it that not more than 2 per cent. of the surviving children in any one year have not had their births notified and recorded. Every effort is made to re-vaccinate all young adults, especially girls before *purdah-nashin* age; and when any case of small-pox (or chicken-pox) occurs the opportunity is immediately seized to carry out wholesale re-vaccination, as it has been found that the villagers at such times willingly submit to this procedure. By these means small-pox has been practically abolished from the Mining Settlement, the death rate from the disease during the year 1922 being *nil*. The Sanitary Assistant also gives weekly lectures in Bengali in the primary schools of his circle on elementary hygiene; and a primer in simple language for that purpose has been compiled by me entitled "*Saral Sastatattwa*," dealing with the following subjects:—

- (1) The Importance of a Pure Drinking Water Supply; (2) Cholera; (3) Typhoid Fever; (4) Dysentery; (5) Malaria; (6) The Importance of Quinine in the Prevention and Cure of Malaria; (7) Small-pox; (8) Plague; (9) Consumption; (10) Flies; (11) Hookworm Disease."

This primer which is printed at the Board's expense is distributed free to all scholars in the primary schools of the Settlement. For delivering these lectures each Sanitary Assistant receives an allowance of four annas per lecture, and the scholars are periodically examined in the subject-matter of the primer by the Sanitary Inspector of the circle, and suitable book prizes are awarded annually to the boy (or girl) in each school shewing the best acquaintance with the subject. Each Sanitary Assistant is provided with a staff of *doms* to keep the burning ghats in his circle in sanitary order, and it is his duty to supervise their work and to see that they carry it out efficiently. Under the Act the Board is empowered to "recognise" and control all burning ghats in the Mining Settlement. On the establishment of the Board in 1916 the most suitable of the existing sites commonly used as burning ghats in the Settlement were selected after due enquiry for "recognition" and the remainder closed. Burning ghats in the Settlement, therefore, consist

merely of suitable pieces of open land in the vicinity of tanks or streams, water being a ceremonial necessity in Hindu cremation. The area of the burning ghat is demarcated with pillars; and due care is taken, in the case of those ghats which border on streams or rivers, that sufficient space is left between high-water level and the ghat for safety, no one being permitted to cremate or bury a dead body outside the limits of the ghat. It is the duty of the *dom* in charge to see that this order is carried out, and that all bodies are thoroughly reduced to ashes or effectively buried. Before the establishment of the Board, cholera was frequently spread in the Settlement by burying the corpses of those who had died of cholera in the sand of river-beds or by throwing uncremated or partly cremated corpses into the stream, but such acts are now things of the past.

In charge of the Sanitary Assistants are six fully qualified Sanitary Inspectors, each Inspector having as a rule two Sanitary Assistants under him. The duties of each Sanitary Inspector consist in the supervision of the work of his Sanitary Assistants and in the sanitary inspection of the collieries in his circle. Collieries are bound by law to give immediate notice to the Board (and to the Sanitary Inspector of the circle) of any case or suspected cases of cholera, small-pox or plague. This notice is sent to the Sanitary Inspector by special messenger and to the office of the Mines Board by post on a special form provided for the purpose.

In cases of epidemic disease in collieries, similar steps are taken by the Sanitary Inspector to those taken by the Sanitary Assistant in villages. The Sanitary Inspector, however, has the assistance of the medical staff in collieries, but where the colliery is small and the staff insufficient or where the colliery is remote from the headquarters of the Sanitary Inspector, the Sanitary Assistant is also requisitioned to see that everything necessary to prevent the spread of the disease is carried out. The Sanitary Inspectors also give systematic lectures, illustrated with magic lantern slides, on public health in the villages of the Settlement during the cold weather and in epidemic times. The Board also employs an anti-malarial staff of six promoted Sanitary Assistants who have been specially trained in the necessary entomology, etc. Throughout the malarious season of the year (July to October) when any outbreak of "fever" is reported from any village by the chowkidar or by the Sanitary Assistant, the anti-malarial investigator is at once sent to that village to ascertain the splenic index, and to examine all the tanks and water courses in and around the village with a view to discovering which of them are infested with malaria-carrying anopheline larvæ. On the investigator's report being received by the Chief Sanitary Officer, a letter is written to the owners of the infested tanks acquainting them of the facts and requesting them to have the tanks cleared of weeds.

This is occasionally carried out by the owners if sufficiently enlightened or wealthy, but in most cases is done by the Board, and where done the epidemic as a rule quickly subsides. A striking instance of this occurred in Bansra village near Raniganj where, in the month of August 1922, the Sanitary Assistant reported that on his weekly inspection that he had found great numbers of the inhabitants confined to bed with "fever." The anti-malarial investigator was accordingly ordered to report at once on the splenic index of the village and on the infestation of the village tanks. On investigation he found that the splenic index was 20 per cent. and that of many tanks in and around the village, one tank only was infested with larvæ of a malaria-carrying species of mosquito (*A. fuliginosus*). At the writer's suggestion this tank was cleansed of weeds by the owners of the village (Messrs. The Bansra Coal Co., Ltd.) at an approximate cost of Rs. 25, and within two months of the cleansing of the tank and without any other anti-malarial measures having been taken, the splenic index of the village had fallen to 9.6 per cent., and at the end of December to 0. This case furnishes a good example of the benefits that can be secured by the scientific direction of effort in public health administration. The malaria-carrying species of mosquitoes generally found in the Mining Settlement are *A. fuliginosus*, *A. culicifacies* and *A. sinensis*, their relative frequency being in the order named.

A staff of three midwives is also maintained by the Board to render gratuitous assistance to the married women of the Settlement before, during, and after confinement. The three midwives have their resident headquarters on collieries in different areas of the Settlement and their chief work lies amongst the colliery population whose houses they visit daily, giving ante- and post-natal advice and assistance to women requiring it and simple lectures in domestic hygiene and cleanliness to others. They also act as vaccinators of *purdah-nashin* women and girls during the vaccination season and whenever small-pox is epidemic.

For the medical inspection of school children a qualified Sub-Assistant Surgeon is employed. When a child at school is found on examination to be suffering from any defect, a written report to that effect is sent home with the child, suggestions being made at the same time for the remedy; and it is satisfactory to note that in a considerable proportion of cases, where the parents are literate, these suggestions are carried out. The percentage of defect found amongst the school children in the Mining Settlement is about 40 per cent.

The organisation of the Mines Board of Health, while essentially rural, has been elaborated to meet the special requirements of the Mining Settlement. For ordinary district public health work a considerably less numerous staff would

suffice; and I give below the outlines of an organisation suitable for such work, originally published by me elsewhere, which can be maintained on a sum representing less than one anna per head of the population per annum.

Presuming that the average district in Bengal is 3,000 square miles in area, which is an *over-estimate*, there would be required according to the scale laid down above:—

	Rs.
1 District Health Officer at Rs. 400 p.m. plus Rs. 150 Travelling Allowance ..	6,600
15 Sanitary Inspectors at Rs. 100 p.m. plus Rs. 30 Travelling Allowance ..	23,400
60 Sanitary Assistants at Rs. 20 p.m. plus Rs. 15 Travelling Allowance ..	25,200
1 Head Clerk and Accountant at Rs. 75 p.m. ..	900
2 Assistant Clerks at Rs. 35 p.m. ..	840
1 Peon at Rs. 15 p.m. ..	180
Stationery, Forms, etc. ..	1,000
Rent of Offices for Sanitary Inspectors and Sanitary Assistants ..	4,600
Medicines, Essential Oils Cholera Prophylactic, Chloride of Lime, etc. ..	3,000
Rewards to Chowkidars for notification of Cholera and Small-pox ..	500
	<hr/> 66,220 <hr/>

Taking the average population of a district in Bengal as 1,250,000—which is an *under-estimate*—a rate equivalent to a contribution of one anna per head per annum would provide no less a sum than Rs. 78,000, an amount which as we have seen above, would be more than sufficient to provide a complete public health organisation for the district.

As an illustration of the value of the work which can be accomplished by such an organisation, I give below a table, compiled from the weekly returns of vital statistics in the *Calcutta Gazette* for the year 1923, shewing the death rates per thousand in the Asansol Mining Settlement as compared with those in Calcutta, Howrah, Dacca and Maniktolla municipalities:—

	Calcutta.	Howrah.	Dacca.	Maniktolla.	Asansol Mining Settlement.
Cholera ..	1.00	1.19	1.32	0.99	0.56
Small-pox ..	0.17	0.09	0.02	0.28	0.015
"Fever" ..	4.09	8.22	11.21	5.46	2.10
Diarrhoea and Dysentery.	2.24	4.44	2.54	3.69	0.83
Respiratory diseases ..	8.91	6.47	2.98	10.24	3.75
TOTAL ..	28.40	28.64	28.33	31.63	17.97

It should be remembered that the Asansol Mining Settlement was once such a hot-bed of disease as to necessitate for its sanitation the establishment of a special Board of Health, the population being annually decimated by a regular succession of epidemic diseases—cholera, small-pox and malaria, in the order named. All that has now been changed, and the Settlement is

probably, at present, the most salubrious area of its size in the plains of India with a death rate which compares favourably with that of many countries in Europe.

IS *TRICHOMONAS HOMINIS* PATHOGENIC?

By Capt. P. GANGULI, B.A., D.T.M. (Bengal),

Teacher of Medicine, Dacca Medical School.

EVER since the discovery of *Trichomonas vaginalis* by Donne in 1837 in vaginal mucus, and of *Trichomonas hominis* by Davaine in 1854 in enteric and cholera stools, opinions have varied as to the pathogenicity of this protozoon. Schaudin was of opinion that *Trichomonas* becomes an amoeba, and this view was corroborated by Gauducheau in 1912, who thought that it was parasitic in the tissues in the amoebic stage, saprophytic in the lumen of the bowel, and a free flagellate in the free living state in stools. It was Gauducheau who found out that *Læschia undulans* of Castellani was really allied to this species. There is no doubt that *Læschia undulans* is nothing but a dying *Trichomonas* in its preliminary stage before rounding up. When a *Trichomonas* loses its active motility, it emits a finger-like protrusion in front and passes it on one side towards the back. This protrusion is then withdrawn near its back and is again emitted in the front. The figure of *Læschia undulans*, given on p. 319 of Castellani and Chalmers's "Manual of Tropical Medicine," shows an undulating membrane, and there is no doubt that this was a picture of a dying *Trichomonas*. Sometimes this protrusion assumes a club-shaped extremity.

There is a general opinion amongst protozoologists such as Dobell, O'Connor, Knowles and others that *Trichomonas* is not pathogenic. Dobell gives three reasons in favour of his assertion:—

(1) He does not consider that these flagellates are more common in cases of diarrhoea than in healthy persons.

(2) These flagellates do not attack the tissues of the host.

(3) No methods of treatment have yet been discovered by which this infestation is removed.

As regards the first point of Dobell, I would like to point out that out of 43 cases in which *Trichomonas* was found in human stools in Eastern Bengal, no less than 36 were suffering from either diarrhoea or dysentery. Stools of three such dysentery cases were "plated" but no colony of dysentery bacilli was discovered. Seven cases with normal formed stools showed motile *Trichomonas*. I consider them carriers in analogy with *Entamoeba histolytica* carriers. Just as some persons may harbour *E. histolytica* without showing any signs of dysentery, so *Trichomonas* may be found in persons passing healthy stools.

Coming to the second point of Dobell, that these flagellates do not attack the tissues of the host, I would like to point out that in six of my cases *Trichomonas* was found to contain red blood cells. These were all cases of diarrhoea, in the stools of which the red blood cells were very scarce, although the occult blood test was positive in all the cases. On the other hand, no red blood cells were found within any *Trichomonas* found in dysenteric stools containing numerous red blood cells. Knowles points out that the presence of red blood cells in *Trichomonas* is no proof of its pathogenicity. But no other non-pathogenic intestinal flagellate has been found to have ingested the red blood cells. Even *Giardia intestinalis*, an admittedly pathogenic flagellate, has not been seen to ingest red blood cells. Again the amoeboid character does not always impart the power of ingesting the red blood cells, as proved by the fact that none of the non-pathogenic *entamoebæ* found in the human stools ingest them, although they have got to wade through the red blood cells when found in dysenteric stools. There is not a single instance of a non-pathogenic amoeba, flagellate or ciliate that I know of which ingests red blood cells. *Balan-tidium coli*, a pathogenic ciliate, ingests red blood cells.

Besides ingestion of red blood cells, there is another point in support of its pathogenicity. Wenyon's discovery of this flagellate set deeply in sections of the mucosa of the human intestine disproves Dobell's second point. Wenyon himself believes that it must have some connection with pathogenicity.

Dobell's third point is the intractability of the infestation to any medication. *Trichomonas* infestation can be easily removed by exhibition of oleum terebinthinæ. All my cases readily yielded to big doses of oil of turpentine given with castor oil emulsion. The patients showing *E. histolytica* in their stools in addition to *Trichomonas* required emetine as well.

There is another interesting point in this connection. In two cases passing dysenteric stools, both *E. histolytica* and *Trichomonas* were found. The pH of both the stools was 6.8. In nearly all the cases the reaction of the stools showing *Trichomonas* was distinctly alkaline; but in these two cases, although the reactions of the stools were acid, the flagellates were found to be as active as ever.

TRICHOMONAS INFECTION IN THE URINE.

By Assistant Surgeon S. K. GHOSH DASTIDAR,
M.B., D.T.M. (Bengal).

General Hospital, Cuttack.

Trichomonas hominis is a well-known intestinal flagellate protozoal parasite of the intestine; and several writers have described infection of the vagina with *Trichomonas vaginalis*. *Trichomonas* infection of the urethra in the male,

however has not been previously described as far as I am aware. In routine examination of some thousand specimens of urine from both sexes, I had never encountered this parasite until recently, but have lately encountered urinary infection in four individuals, three of them males. These cases were as follows:—

Case 1.—B. C. S., Hindu male, aged 62 years. On March 16th, 1924, the urine gave a specific gravity of 1010; reaction slightly acid; a trace of albumin present; no sugar. Microscopic examination of the deposit shewed a few pus cells and numerous and actively motile *Trichomonas*. On the 21st April, 1924, the urine was neutral in reaction; neither albumin nor sugar was present, and neither pus cells nor *Trichomonas* could be found.

Case 2.—S. B., Mahomedan male, aged 50 years. On the 24th May 1924, the urine had a specific gravity of 1005 and an acid reaction; shewed no albumin or sugar; and on microscopic examination a few pus cells and *Trichomonas*. On the 13th July 1924 the reaction was neutral; and neither pus cells nor *Trichomonas* were found.

Case 3.—N. M., Hindu female, aged 19 years. On the 8th November 1924, the urine had a specific gravity of 1010 and acid reaction; shewed no albumin or sugar, but many *Trichomonas* on microscopic examination of the deposit.

Case 4.—S. C., Hindu male, aged 40 years. On the 20th January 1925, the urine had a specific gravity of 1008 and acid reaction; shewed no sugar or albumin; but on microscopic examination some pus cells and numerous *Trichomonas*.

All the samples of urine were collected in clean glass urinals by myself, so no question of faecal contamination can arise. It is interesting to note that in two instances where a second examination was carried out, the infection had spontaneously cleared up within a short time, without any treatment, and that the pus cells present at the first examination when *Trichomonas* was present, were absent at the second examination when it was absent. It would appear that *Trichomonas* may cause a mild urethritis, attended with smarting and burning on micturition, or the discharge of pus per urethram, but that this urethritis cures itself on the disappearance of the *Trichomonas*.

ON THE TECHNIQUE AND SIGNIFICANCE OF THE ROSINDOLE REACTION, APPLIED TO URINE.

By A. NEAVE KINGSBURY, M.B., B.S. (Lond.),
D.P.H., D.T.M. & H.,

Pathologist, Institute for Medical Research,
Kuala Lumpur,

and

K. KANAGARAYER, L.M.S. (S'pore).

THE derivatives of tryptophane, which are known to be formed by putrefactive bacteria in the intestinal canal, are indole-propionic acid, indole-acetic acid, indole and skatole. Small quantities of indole are absorbed and undergo

further oxidation to indoxyl, which is excreted in the urine combined with sulphuric acid (indican) and glycuronic acid. The formation of indican is thought to be one of the many functions of the liver, and the quantity present in the urine is regarded as an index of the degree of intestinal stasis. It is probable that other derivatives are also absorbed from the alimentary canal. Putrid purulent conditions are sometimes accompanied by an increase in urinary indican, and this observation has been cited as evidence that endogenous formation may occur.

The purpose of the present paper is to point out that products of tryptophane, other than indican, are frequently present in urine and that variation in the excretion of these products appears to have some correlation with certain pathological conditions.

Since indole production has been regarded as a determinative characteristic in bacteriology, considerable research has been carried out on the indoles and their colour reactions. Ehrlich's rosindole test has been found delicate, but is also given by tryptophane and many of its derivatives, though confusion is unlikely to occur with skatole as a blue violet tint is produced instead of the usual rose colour.

It has been suggested that the rosindole reaction could be rendered more specific by its application to a distillate, as tryptophane and indole-acetic acid are non-volatile in steam, while indole and skatole are known to be readily volatile. Working along these lines Goré¹ devised the ingenious cotton wool plug (C. W. P.) test for indole, which was shown by Malone and Goré² to give positive results with an indole dilution of one part in two million.

In a recent communication to the Medical Research Section of the Indian Science Congress, Goré³ suggested that the application of the cotton wool plug test to urine would serve to indicate the presence of indican, but based this conclusion on the parallel results obtained with his test and the Obermeyer test for indican on ten specimens only. For the convenience of readers Goré's technique of the cotton wool plug test for urine is given below:—

"Put 2 c.c. of urine into a small test tube (5 ins. by $\frac{3}{4}$ in.) and fit it with a plug made of white absorbent cotton wool. Remove the plug, moisten its under-surface with a drop or two, first of potassium persulphate solution (potassium persulphate 1 gm.; distilled water 100 c.c.) and then of p. dimethyl-amino-benzaldehyde solution (p. dimethyl-amino-benzaldehyde 1 gm.; absolute alcohol 95 c.c.; concentrated hydrochloric acid 20 c.c.), and replace it. Bring the urine to the boil by intermittent heating in a low flame, and if the urine contains indican, half a minute or a minute's further such boiling imparts a pink colour to the moistened under-surface of the plug. In the case of a negative result, i.e., absence of indican, no pink colour is seen on the cotton wool."

If Goré's test can be applied for urinary indican, either indican must be volatile and capable of giving the rosindole reaction, or variations in the excretion of indican must be accompanied by similar variations in the excretion of a volatile rosindole-positive substance. That indican is non-volatile was demonstrated by the writers in the following experiment:—

400 c.cms. of pooled urine which gave positive results with both the cotton wool plug and the Obermeyer tests were slowly distilled until 200 c.cms. were obtained. Both distillate and residue were made up to the original volume with distilled water so that the volatile and non-volatile constituents respectively were in the same concentration as in the original urine. The diluted distillate gave the cotton wool plug reaction to the same degree as the original urine but was negative to the Obermeyer test, while the diluted residue did not give the cotton wool plug reaction but the Obermeyer test was positive as in the original urine. The cotton wool plug reaction, therefore, cannot be given by indican.

In order to determine if the excretion of a volatile rosindole-positive substance was paralleled by the excretion of indican we have carried out a series of upwards of 250 rosindole tests by the modified technique described below which will be referred to as the R. I. test. Each urine was also tested with Obermeyer's reagent for indican. The specimens were obtained from Chinese and Tamil patients in the admission ward of the District Hospital, Kuala Lumpur, and we desire to acknowledge our indebtedness to Dr. E. A. O. Travers for the clinical material.

A graphical comparison between the results of the two tests is shown in Chart I, from which it is seen that no relationship exists between the excretion of indican and the volatile rosindole positive substance.

CHART I.

A graphical comparison of the results from the R. I. and Obermeyer Tests.

What, then, is the substance present in a large percentage of urines which gives a positive R. I. test? To isolate it, a large quantity of pooled urine was distilled and the distillate thoroughly extracted with neutral ether, which was allowed to evaporate at room temperature, leaving a fine film at the bottom of the flask. The extracted distillate no longer gave a positive R. I. reaction, and the ether-soluble residue was found to contain indole though it is possible that traces of other volatile, ether-soluble, rosindole-positive substances were also present.

A simplified technique for the urinary rosindole test.

In carrying out our series the cotton wool plug was found to be inconvenient, and it was early superseded by a diaphragm of filter paper over the mouth of the test tube, held in position by an indiarubber ring. Three drops of the persulphate solution were placed on the diaphragm followed by three drops of the p. dimethyl-amino-benzaldehyde solution, delivered by a small pipette. This modification has the advantage that the result can be read directly by viewing the upper surface of the diaphragm. Intermitent boiling over an open flame was tedious and liable to give varying results. We therefore employed a water bath and all tubes were placed in boiling water for seven minutes before reading. The rose colour tends to fade after removal of the tubes from the bath, so that readings should be made immediately after removal.

We found that the test could be rendered quantitative as the gradations of the rose colour obtained approximate very nearly to the shades produced by dipping filter papers in very weak solutions of neutral red. The neutral red papers are standardised by matching the tints obtained by applying the test to known indol solutions, and are then compared with the colours given by the urine under test. The disadvantage of this method is the tendency of neutral red to fade, which necessitates re-standardisation from time to time.

Correlation between the results of the rosindole test and clinical diagnosis.

The readings of the R. I. and indican tests in various diseases are shown in Table I, from which all "trace" readings have been omitted. The results indicate possible clinical applications of the R. I. test, though the number of cases in each group is too small for the drawing of any definite conclusion.

In the respiratory diseases (25 cases)—pneumonia, influenza and tuberculosis—there is a slight increase in the percentage of R. I.-positive cases, and it is noteworthy that all the cases of tuberculosis, including seven pulmonary and two bone infections, gave positive R. I. tests, while only in three cases was a positive indican result obtained.

The nephritic cases (16) included sub-acute nephritis and two cases of chronic interstitial

nephritis. The results in this group are of interest because the percentage of R. I.-positive cases is considerably decreased, but the indican results show little variation from the average over the series. Possibly the nephritic kidney is unable to excrete the R. I.-positive substance as readily as the normal kidney.

The liver insufficiency cases (7)—cirrhosis and abscess—show a largely increased percentage

(1) Whether sodium iodide orally was beneficial in cases of goitre.

(2) Whether iodine is essential for the good functioning of the thyroid gland.

(3) Whether the oral administration of sodium iodide could prevent the disease.

He suggested that it might be advisable if the drug was administered intravenously, pointing out further that no possible harm could be done

TABLE I.

Showing the results of the R. I. and Obermeyer Tests in various Diseases.

	All Cases.	Malaria.	Respiratory Diseases.	Nephritis.	Alimentary Diseases (Dysentery, "Indigestion," and Constipation).	Liver Diseases (Cirrhosis and Abscess).	Sepsis (Ulcers, Abscess, Cellulitis, etc.).	Syphilis.
No. of Cases	265	98	25	16	21	7	16	19
Indole + (R. I. Test)	52%	49%	56%	31%	67%	71%	50%	58%
Indole - (R. I. Test)	16%	18%	12%	38%	0%	0%	6%	16%
Indican + (Obermeyer Test) ..	38%	36%	32%	44%	38%	29%	44%	47%
Indican - (Obermeyer Test) ..	42%	43%	40%	44%	24%	43%	38%	42%

of positive cases while the indican positive percentage is slightly decreased; a result which is not at variance with the theory that the formation of indican from indole occurs in the liver.

The results obtained in other diseases require little comment.

Summary.

A technique for the application of the rosindole test to urine is described.

A positive result does not indicate the presence of indican in the urine.

The percentage of positive cases is decreased in nephritic cases and increased in liver insufficiency cases.

INTRAVENOUS INJECTIONS OF SODIUM IODIDE IN THE TREATMENT OF GOITRE.

By E. A. DAVIES,

LIEUT., I.M.D.,

Civil Surgeon, Chin Hills, Falam,

and

P. BELL, I.M.D.

Assistant Surgeon.

The junior writer first broached the subject of intravenous injections of sodium iodide for the treatment of goitre with a view to testing:—

if no benefit was obtained, the drug being alkaline and non-poisonous. Accordingly we agreed to test the treatment, for which purpose the senior writer visited one of the villages close to Falam, and selected two cases (Nos. 4 and 5) of goitre, about the size of an orange each. On his return he found two other cases had applied for treatment for goitre (Nos. 2 and 3); these were old-standing cases and very much larger than Nos. 4 and 5.

Of the two sets, Nos. 3 and 4 were selected for intravenous treatment for the following reasons:—

Case 3.—The woman was normally developed and the goitre was not circumscribed and hard, whereas in case 2 the woman was partially a cretin and mentally affected to a certain degree.

Case 4.—The boy being older than case 5, we expected that the veins would be easier to deal with. Otherwise there was not very much to choose between the two goitres.

All the cases will be discussed in turn, and it is hoped that in a short time we will be able to add a long list to this short one. Our reasons for publishing our results so early are two-fold:—

(1) To enable other workers to take up the experiments.

(2) To try and get the drug in as pure a form as possible, also in a more portable form than the powder at present in use.

The drug has been administered intravenously without any previous preparation, though the

patients are treated in the morning on an empty stomach.

For the first dose 10 grs. was used and administered to case 3. She had a slight rigor with a temperature of 100.4° F. It was then decided to lessen the dose. Five to 6 grs. intravenously is tolerated well without any reaction: a solution of 1 gr. to 1 c.c. of distilled water is used. In fact a few cases under treatment now attend hospital as out-patients, attending every fourth day for injection. They return to their villages a few hours after receiving the injections, without any ill-effects. During the intervening days they are given the drug by the mouth (2 grs. three times a day). This they declare they take regularly. The result of these cases will be published later.

The reasons for adopting this measure of treating these patients as out-patients are that:—

(1) Chins will not come into hospital unless they are dieted.

(2) They cannot be away long from their fields and homes for such a trivial thing (to them) as a goitre.

(3) So far they are convinced that nothing can be done to cure goitre.

(4) On the whole they do not suffer much inconvenience from the disease.

(5) There are a few among them who suffer mentally, but the cause is not ascribed to goitre, by the Chin.

(6) They usually apply for treatment only when the goitre is painful, or when there are symptoms due to pressure.

(a) When the goitre is painful they hope to get relief, or the goitre may suppurate.

(b) When very large, they have been sent back without relief. For this latter condition nothing can be said on the subject at present, as a very large goitre with urgent pressure symptoms has not been experimented on so far.

Case 1 came to hospital voluntarily because the goitre was painful. Cases 2 and 3 came to hospital voluntarily as they were suffering from various indefinite pains all over the body which they thought were due to the goitre. Cases 4 and 5 were ordered to hospital by their chief. Case 6 applied for treatment because his goitre was painful. Case 7 applied for treatment because she was weak, anæmic and stated she had pressure symptoms. Case 8 was similar to case 6. Case 9 applied for treatment after cases 2 and 3 returned to their villages; but this case wanted to be operated on and would not remain in hospital for a full course of treatment.

Case 1.—Kap Lio, aged 35, Burmese male, was admitted on 30-1-1924 from Low Chang village. Large painful goitre. No suppuration. Local application, glycerine and belladonna. Intravenous doses of tincture of iodine given:—

18-2-1924	m. 6
21-2-1924	m. 8
23-2-1924	m. 9
25-2-1924	m. 9
28-2-1924	m. 9

Immediate results—no appreciable decrease.

This patient was ordered to attend hospital on 5-9-1924 for inspection. He had now got a goitre only about the size of a bean. The tincture of iodine treatment was not tried on other cases as this man could not be got hold of before. It is evident that tincture of iodine acts in the same manner as sodium iodide. On admission this man's goitre was very large.

Case 2.—Mangell, aged 25, Burmese female, was admitted on 3-5-1924 from Kholai village. The patient was dwarfed but well developed. History of goitre in grandmother, mother and sister. The goitre was large, lobulated and hard. She was a cretin to a certain degree, and was slightly deficient mentally.

Treatment adopted:—

Sodium iodide grains 8, t.d.s., orally.

7-5-1924: Sodium iodide stopped. Placed on thyroid extract (2½ grs. each), two tablets daily.

10-5-1924: 1½ tablets daily.

9-5-1924: Subcutaneous injection of sodium iodide, grs. 6.

12-5-1924: Subcutaneous injection of sodium iodide, grs. 6.

The patient could not understand why her sister was being given injections, whereas she was receiving none. For this reason she was given the subcutaneous injections; these also proved that a subcutaneous injection of sodium iodide produced no ill-effects and that while giving an intravenous injection, if the vein is accidentally missed no harm results.

19-5-1924: Thyroid gland extract discontinued. Put on to sodium iodide by the mouth again.

Discharged on 17-6-1924. The patient was improved to a certain extent. On the 10-9-1924 the patient was again seen, and it was found that the goitre was only the size of a walnut. She is now undergoing a further course of treatment.

Case 3.—Kwathing, aged 25, Burmese female, admitted on 3-6-1924 from Kholai village; sister of case 2; well developed, goitre not hard.

Intravenous injections of sodium iodide:—

5-6-1924	grs. 10.
8-6-1924	grs. 7.
12-6-1924	grs. 8.
19-6-1924	grs. 6.
27-6-1924	grs. 6.
11-7-1924	grs. 6.

The patient was given sodium iodide orally as well.

In this case there was a certain amount of reaction after some of the doses. Discharged on 17-7-1924 with a certain amount of improvement. Seen again on 10-9-1924. It was found that the goitre had practically disappeared. She is under treatment for a further course.

Case 4.—Kathwan, aged 13, Burmese male, admitted on 4-5-1924 from Songte village, goitre about the size of a small orange.

There are a number of cases of goitre in this village.

Intravenous injections of sodium iodide:—

7-5-1924	grs. 4.
10-5-1924	grs. 5.
19-5-1924	grs. 5.
25-5-1924	grs. 5.

The patient was also given a certain amount of sodium iodide orally. Discharged from hospital on 3-6-1924. Goitre on discharge from hospital was reduced somewhat: seen again a month and a half later, the patient had no signs of goitre whatsoever, his neck being quite normal.

Case 5.—Neikwal, aged 8, Burmese male, admitted on 4-5-1924 from Songte village. This case was treated orally for the same period as case 4 and was discharged from hospital on the same date, i.e., 3-6-1924. Was not given sodium iodide intravenously. When seen a month and a half later the patient's goitre was much reduced, but had not been completely reduced. He was then given a further course of three intravenous injections of sodium iodide, grs. 5 each. The goitre after this disappeared completely.

Case 6.—Phunlul, aged 25, Burmese male, admitted on 5-5-1924 from Tung Thu village.

The patient came to hospital with symptoms of suppurating goitre. This was incised and drained. Steady uninterrupted recovery.

Case 7.—Naokim, aged 32, Burmese female, admitted on 12-5-1924 from Tashon village.

Patient gave a history of fever. Was very anæmic and stated that she was unable to swallow properly. From the onset she was treated for her anæmic condition, in addition to being given sodium iodide. The size of the goitre was larger than an orange.

Intravenous injections of sodium iodide:—

13-5-1924	grs. 6.
16-5-1924	grs. 6.
28-5-1924	grs. 6.
11-7-1924	grs. 6.
18-7-1924	grs. 6.

On 2-6-1924 sepsis supervened. A small abscess formed; this was incised on 15-6-1924 and it healed before her discharge from hospital. She was seen on 4-9-1924 and it was found that the goitre was the size of a bean. Refused further treatment as she said her mother could not spare her from her fields.

Case 8.—Ramshuar, aged 45, Burmese male, admitted 14-5-1924, absconded 11-7-1924. This was a protracted case of suppurating goitre. The gland was very large and the whole of it suppurated.

No internal treatment was given to this case. Shortly before he absconded he came out with an eczematous rash about the neck and chest, and in fact wherever the pus from his goitre touched his body. He was being treated for this condition when he disappeared from hospital and has not been seen since. The patient was mentally deficient to a marked degree.

Case 9.—Tialchi, aged 15, Burmese female, Kholai village. The patient applied for treatment from the same village as cases 2 and 3, after seeing the improvement in these cases: her goitre was small. She was given two intravenous injections of sodium iodide, grs. 5 each. She asked for an operation, and as this was refused her she would not remain in hospital for further treatment. She was seen again on 10-9-1924; the goitre had almost disappeared in spite of her having received only two injections of sodium iodide.

Points of importance are:—

Whether after the goitre has been reduced to normal, is it going to remain so, or is it going to recur?

We are of opinion that it is going to recur, so long as the patient remains in his original surroundings. Even if all the cases do not recur, a greater majority are bound to recur.

Granted that after a cure the patient is moved to a more suitable place with a varied diet there may be no recurrence. We are dealing with the Chin and we know that this cannot happen here. The Chin is too poor, too ignorant, too attached to his village, surroundings and customs to migrate. He does not wish to separate himself from his village if he can possibly help it. So that other means must be found for the prevention of the

recurrence. This is most essential, otherwise all the good done will be undone when such patients find that their disease recurs, after they have submitted to intravenous treatment.

If sodium iodide could be issued in tablet form it would be convenient and could be used as follows:—

(1) The hospital could keep a stock for those who wish to apply for the drug and to take it, say for a short period, 2 or 3 times yearly.

(2) The sub-assistant surgeons in charge of the travelling dispensaries could carry a stock of the same tablets and issue them in villages to all patients previously treated.

(3) The Political Department could be given the drug for distribution, or sale if desired, to villages. They could arrange with the village chiefs with regard to the supply of the same.

A chemically pure supply of the drug is necessary for intravenous injections to ensure safety.

It will be seen from case 1 that tincture of iodine acts in the same manner as sodium iodide. The benefit of using the tincture is that it is practically aseptic, but it is likely to cause irritation to the tissues to a certain degree; if a vein is missed this would clear up, though only after a short interval. With sodium iodide, unless the drug is chemically pure, we cannot say what we are introducing into the vein. In its favour is the fact that it does not cause irritation. We have experimented with it subcutaneously and find that there are no ill-effects from this method, in fact it may have benefited case 2 considerably.

Besides the three patients now attending hospital, three other cases are being treated as in-patients at present. Since writing this article several other cases have recovered after intravenous treatment of a similar character.

A Mirror of Hospital Practice.

THE TREATMENT OF MALARIA IN PREGNANT WOMEN.

By J. DHAIRYAM, L.M.S.,

Medical Officer, Base Hospital, Narsapatam, Vizagapatam.

THE treatment of malaria in pregnant women was formerly a bugbear to me; and my difficulty knew no bounds when I was faced with a case of malaria in a woman pregnant some 7 or 8 months and with a temperature of 104 to 105° every other day. Especially great is the difficulty if the patient is a poor woman and cannot afford to get out of the malarial tracts.

In medical practice quinine is the drug which causes cures in malaria, but it is also a drug which is stated to cause abortion. The small doses of

2 to 3 grains daily of quinine advocated by some medical men for this condition are useless, whilst malaria by itself may bring on the abortion which we dread under quinine therapy. Also the continued malaria shatters the patient's system and renders it difficult for her to pass safely through the critical period of delivery.

In tackling such cases I have hit upon a method of treatment which I have found valuable and reliable during the past three years in the Agency Tracts of Madras, an area where malaria is both rife and severe, and where almost every pregnant woman gets one or more attacks of malaria during her pregnancy. It is as follows:—

(1) The bowels having been well opened by castor oil or calomel, 10 grains of potassium bromide are given in solution.

(2) Half an hour later 10 grains of acid hydrochloride of quinine is given by intramuscular injection, together with a second dose of 10 grains of potassium bromide in solution by the mouth.

(3) Half an hour after the injection, a third dose of 10 grains of potassium bromide is again given in solution orally.

This course is repeated on the second day. From the third day onwards I give 10 grains of potassium bromide, followed half an hour later by 7 grains of quinine sulphate, both in solution and given orally three times a day.

Since adopting this method I have never experienced difficulties in the treatment of malaria in pregnant women, and have had no failures of treatment. Extract *Prunifolium Viburnum Liquidum* may be added to the bromide mixture if desired, but the simple bromide mixture in itself is sufficient. Whatever the experience of others, if proper precautions are taken with regard to asepsis, I have never seen bad results to follow such intramuscular injections of quinine.

AN INTERESTING CASE OF ORIENTAL SORE.

By D. N. BASU, M.B. (Cal.), D.P.H. (Camb.), D.T.M. (Liverpool),

Honorary Visiting Physician, Voluntary Venereal Diseases Hospital, Alipore, Calcutta.

A HINDU girl aged 5, with a sore on her right cheek was brought to me in Calcutta for consultation at the end of November 1924. At that time there was no evidence of any crust on the sore, but a definite inflammatory marginal zone was present. The glands of the neck were enlarged. On enquiry I was told that she had never been out of Calcutta, and I gave instructions that I would see the case again a fortnight later.

She was again brought to me on the 20th December, 1924. By this time the sore had increased considerably in size, and there was a very marked scab. I punctured the edge of the sore and found *Leishmania tropica* parasites present.

On further pressing enquiries, it transpired that the patient had left Calcutta in the third or fourth week of October 1923, halting on her way at Benares for a couple of days. She reached Ferozepore in the Punjab at the end of October

1923. There she had an attack of fever—(cause undiagnosed)—but recovered in a week's time and returned to Calcutta at the end of November 1923. She kept in good health, except for an occasional attack of fever of mild type, until February 1924, when a vague type of skin disease appeared. In April 1924, she had an attack of what was diagnosed as chicken-pox. Early in June 1924, a papule appeared on the right cheek, which ultimately enlarged into the lesion shewn in the photograph (January 1925), and shewed numerous *L. tropica* on examination. Thus the incubation period of the lesion was apparently some six and a half to seven months, since Calcutta is not an endemic centre of oriental sore.

The patient was taken to the laboratory of Major R. Knowles, I.M.S., Professor of Protozoology, Calcutta School of Tropical Medicine, who independently confirmed the finding of *L. tropica* in films from the lesion. Cultures on N.N.N. medium from the exudate of the lesion gave a rich growth of the same parasite in its flagellate form. The patient's spleen was not enlarged, and there was no fever at the time of examination, but, on Major Knowles' suggestion, cultures of the peripheral blood were taken by Row's method in order to exclude the possibility of the lesion being one due to "dermal

leishmanoid," caused by *L. donovani* and following on unrecognised kala-azar. These cultures of the venous blood, however, remained sterile and negative and the lesion was clearly due to *L. tropica*. The case is of interest in that the period of incubation can here be definitely established as having been 6½ to 7 months. A second further point of interest in the case is that, when some 50 films from the cultures of *L. tropica* taken from this case were distributed to the current D. T. M. class at the Calcutta School of Tropical Medicine and stained and examined, in one of them a very curious "inversion" form of the parasite was seen. This single herpetomonad form of the parasite had its micronucleus situated posterior to—and not, as usual, anterior to—the macronucleus. Major Knowles has subsequently seen a similar inversion form in a culture of *L. donovani*. It is well known that *Trypanosoma rhodesiense* is capable of shewing such similar inversion forms, with the macronucleus situated towards the non-flagellar pole and posterior to the micronucleus; but this is apparently the first instance to be recorded of a herpetomonad parasite shewing a corresponding peculiarity. What the significance of such inversion forms is, is quite uncertain.

My thanks are due to Major R. Knowles, I.M.S., and to Temporary Assistant Surgeon B. M. Das Gupta, L.M.P., Assistant Professor of Protozoology, Calcutta School of Tropical Medicine, for investigations into the case.

A CASE OF ACUTE GASTRO-DUODENAL ILEUS.

By Capt. R. V. RAJAM, M.B., B.S., Tanjore.

AN Indian Christian, male, aged about 50 years, was admitted to the Headquarters Hospital, Palamcottah, with what appeared to be acute intestinal obstruction. He gave a history of flatulent dyspepsia with epigastric discomfort for nearly six or seven years before the onset of his acute condition. On the night of the attack, some hours before, he had partaken of an unusually heavy meal at a feast. The attack commenced with acute pain in the abdomen and vomiting.

Condition on Admission.—The patient was a lean emaciated man. The abdomen was enormously distended. The distension was more marked in the centre of the abdomen, from the epigastrium to the symphysis pubis. He was vomiting frequently small quantities of bile-stained fluid mixed with undigested pieces of meat and rice. His facies was typical of some acute intra-abdominal trouble. The temperature was subnormal. The pulse was small in volume and 110 to the minute. There was no rigidity of the abdominal wall but diffuse tenderness all over the abdomen, especially marked in the supra- and sub-umbilical regions. There was no visible peristalsis. The

pain was diffuse and continuous. A large and high enema of soap and water gave a good result, but the distension and vomiting were unaffected even by repeated enemas. The patient was prepared for a laparotomy. The abdomen was opened by a sub-umbilical para-rectal incision on the right side. A distended viscus presented at the opening. The incision was enlarged upwards for better exploration. It was found that the stomach was enormously distended. It filled the whole abdominal cavity, its greater curvature reaching to the brim of the pelvis. There was no peristaltic movement visible. On manipulation a splash was elicited. With great difficulty the distended paralysed stomach was lifted and gentle exploration revealed a distended duodenum up to its junction with the jejunum. The duodenum looked more like a distended colon. All the coils of the small intestine as well as the cæcum and part of the ascending colon were in the pelvic cavity and completely collapsed. There was no evidence of any ulcer in the stomach. There was nothing to show the presence of any mechanical obstruction by bands or internal hernia. The abdomen was closed by through and through stitches as the patient's condition was bad, and as I did not understand what I should do for the condition. As soon as the patient recovered from the anaesthetic, he was placed in the Trendelenburg's position and gastric lavage was commenced. It was repeated every two hours. Injections of pituitrin and eserin salicylate were given four-hourly. The patient's condition did not improve and he died 48 hours after the operation. A post-mortem examination could not be had as the relatives took away the body.

A reference to the ordinary text-books on surgery did not help me to understand the cause of this condition. Paralytic ileus of the stomach has been met with as a post-operative complication, especially after operations on the upper abdomen and biliary passages. But in this case there was no such antecedent cause except the history of epigastric discomfort and flatulent dyspepsia. Then Mr. Wilkie's article on chronic gastro-duodenal ileus in the *British Journal of Surgery* and his subsequent lecture on the same, published in the *British Medical Journal* of 1922 enlightened me on the pathogenesis of this condition. According to him the condition is not very rare, but the symptoms have been mistaken for gastric or duodenal ulcer. The disease runs a chronic course, often extending over years, with a great tendency to an acute and fatal exacerbation. It is due to the pressure of the superior mesenteric vessels on the terminal part of the duodenum, which they cross almost at right angles. Normally with the abdominal viscera in their proper place and with a normal tonic condition

of the abdominal muscles, this vascular arch does not exert any mechanical pressure on the duodenum. But in conditions where there is a general visceroptosis, especially of the small intestines and proximal colon, the tension on the mesentery caused by the dropping down of the intestines acts on this vascular arch and compression and mechanical obstruction set in. In the case cited it was observed at the operation that there was marked visceroptosis of the small intestines and proximal colon into the pelvic cavity; and it is quite probably the root cause of the condition. The history of flatulent dyspepsia and epigastric discomfort for a number of years shows that he had been suffering from chronic gastro-duodenal ileus as a result of the visceroptosis. The acute and fatal attack for which he sought admission to the hospital had supervened on the chronic condition. As I was quite unaware of this, I did not look for the arch of the superior mesenteric vessels crossing and compressing the terminal part of the duodenum at the time of the operation. Further, even if the condition had been recognised, the state of the patient was such that no anastomosis operation would have been possible. Operation is not indicated in the acute variety. Only gastric lavage with the patient turned on the face to relieve the pressure on the duodenum has been recommended, and has met with success.

The symptoms of the chronic cases are very liable to be mistaken for gastric or duodenal ulcer, though the latter may arise as a late complication. A long-standing history of flatulent dyspepsia with epigastric discomfort rather than actual pain, with intervals of relative freedom should always raise the suspicion of duodenal ileus. Operative treatment has given the best results in chronic cases. Colopexy suffices to cure the condition in those cases where the tension on the mesentery is due to a mobile and prolapsed proximal colon. But in cases where the drag is due to the prolapse of the small intestines, a duodeno-jejunostomy has given the best results, that is to say anastomosis of the third part of the duodenum proximal to the obstruction to the first coil of the jejunum.

A CASE OF INTESTINAL OBSTRUCTION ASSOCIATED WITH THE FOSSA DUODENO-JEJUNALIS.

By J. B. VAIDYA,

CAPTAIN, I.M.S.,

Medical Officer in charge, Cantonment Hospital, Deolali.

R. P., aged 30, was admitted to hospital for intestinal obstruction of two days' duration. He

had constipation during the period and pain; did not pass any stools or flatus. Vomiting was rare and occurred twice or thrice during the whole period before the admission. The abdomen was hard, distended and tender. The distension was all round the abdomen for a distance of three inches and looked globular. The hernial apertures were normal.

The abdomen was opened in the middle line below the umbilicus. On opening the peritoneal cavity, no coils of small intestine were visible; but instead a glistening tense tumour was noticed occupying the middle of the abdomen, extending more to the left side and coming down to about one inch below the umbilicus. The incision was extended upwards. The small intestine was found enclosed inside this tense sac. The sac was opened and the small intestine came out with a little straw-coloured fluid. The sac had formed recent adhesions all round and these were easily broken with the finger. The intestines were distended, and in one part showed slight discolouration. The large intestine was empty. In the duodenal region there was noticed a constricting band under which the small intestine had passed. This band was divided between ligatures and part of the sac cut. The contents of the small intestine were let out and the opening in it sutured up. The abdominal cavity was closed after introducing into it saline and a drachm of ether.

The patient was in a poor condition when he left the table, but rallied with injections of saline and glucose, and pituitrin. Stimulants were given as required.

After 12 hours the man passed soft stools per anum. He continued to pass stools per rectum, but the second day after the operation the stools were very frequently passed in small quantities.

The wound was inspected on the second day after operation and looked clean. There was a little distension of the abdomen; but no rigidity of the abdominal wall was noticed and there was no tympanites. However, the general condition was very poor and the man died on the third day after the operation.

As regards the nature of obstruction, I think that the small intestine got into the fossa duodeno-jejunalis and pushed out the peritoneum in the form of a sac in which it was enclosed.

Treves, in his "Surgical Applied Anatomy," says:—"The commencement of the jejunum presses into the fossa (fossa duodeno-jejunalis), enlarges its cavity and ultimately separates the peritoneum from its posterior attachments; more and more of the small intestine passes into the increasing pouch until at last nearly the whole of the small intestine may be found lodged in an enormous median retro-peritoneal sac, the mouth of which is the orifice of the fossa duodeno-jejunalis. The duodenum can be seen to enter the sac and the end of the ileum to leave it. The sac usually extends downwards on the left side and may reach the promontory of the sacrum."

I have to thank Colonel R. H. Lloyd, A.D.M.S., Bombay District, and Lieutenant-Colonel A. C. Adderly, D.S.O., R.A.M.C., S.M.O., Deolali, for allowing me to publish this case.

A CASE OF RECURRING AND ENCYSTED VESICAL CALCULUS.

By S. KANTHIMATHY NATHAN, L.M.P.,
Resident Medical Officer, Government Headquarters Hospital, Anantapur.

A young lad by name Naranappa, aged 16 years, was admitted to this hospital on the 3rd December, 1924, for a persistent fistulous opening in the hypogastric region, through which urine was always dribbling and soiling his clothes. On the 13th March, 1921, he had been previously admitted to the same hospital for stone in the bladder, and a big stone weighing 6 drachms 13 grains was removed by suprapubic cystotomy. The bladder and abdominal walls were closed, and the boy was discharged cured on the 19th March, 1921, the wound healing by first intention. For two years he did well and passed urine quite comfortably. In the middle of 1923, he began to experience the old urinary trouble and began to be quite uncomfortable and suffered much from difficult micturition. About the month of January 1924, he felt excruciating pain in the hypogastric region which began to swell up. On applying poultices the swelling gave way at the site of the previous operation by ulceration, through which urine came out freely. A fairly big stone was perceptible through the wound. This state of affairs continued for some time. In the month of September 1924, on a particular day, there was acute retention of urine owing to the blockage of the suprapubic wound by the stone and urethral obstruction as well. When the boy strained to his utmost in his anxiety to drive his urine out, out came a big stone through the abdominal wound with a rush of urine. The boy says that, as the result of the stone coming out through the abdominal wall, a big ulcer was formed and it had not healed, but had left a fistulous opening.

At the time of admission it was found that a small fistulous opening, surrounded by thick scar tissue $2\frac{1}{2}$ in. by $1\frac{1}{2}$ in. in area, as a result of a long-standing ulceration, ran into the bladder. The boy brought with him the stone said to have been passed through his abdominal opening. It weighs 7 drachms and 50 grains and is of phosphatic origin.

For about ten days under antiseptic dressings the fistulous opening shewed no sign of healing. On passing a probe through the fistula, it went deep into the bladder and hit on a stone in the bladder. It was found by sounding per urethram that some more stones were encysted at the mouth of the bladder, making

it difficult to pass the sound into the bladder. Rectally two stones were felt in the prostatic region and grated on each other on moving. On trying to wash out the bladder, the boric lotion did not pass freely inside, neither did it fill the bladder. A grooved director was passed through the fistulous opening until it impinged on the stone, and the bladder was laid open with a knife passed along the director. On passing the finger into the bladder, the stone was not lying free on the cavity but was found encysted under cover of the mucous membrane in the posterior wall near the neck of the bladder. The cavity of the sac containing the stone communicated with the bladder through a small opening. This opening was enlarged and two phosphatic stones weighing 1 drachm 45 grains were removed with some difficulty. The bigger one of the two stones had to be pushed into the bladder by insertion of the finger into the rectum.

The suprapubic wound is healing well and the boy now passes most of his urine through the urinary passage.

I am much indebted to Dr. U. Ganapathi Rao, B.A., L.M.S., District Surgeon, Anantapur, for his kind permission to publish this one of his operation cases, which is unique on account of the recurrence of the stone three times (the last one being encysted) in the course of three years in such a young boy.

HÆMOPLASTIN IN HÆMORRHAGE.

By KAMAKHYA PRASAD LAHIRI, L.M.S.,
Bera P. O., Pabna District.

PHYSICIANS practising in the mofussil are often confronted with cases of hæmorrhage of obstinate type from different organs of the body; and are often put to great anxiety in their treatment, especially with the slender resources at their disposal.

Some time ago, I had to deal with a patient, a Brahmin lady, 50 years of age, suffering from uterine hæmorrhage. She had had a female child 30 years before, which had died within a few days of its birth. I suspected a hæmophilic taint, as she gave a history of profuse bleeding from the gums some three years previously, which had only been arrested with difficulty. She had consulted a specialist in Calcutta who could find nothing abnormal in the internal genitalia, but she stated that she had been losing a considerable quantity of blood daily for the previous 20 days. In fact menstruation had not stopped but had become almost continuous, with passage of fluid blood, and sometimes of clots. She was extremely anæmic on examination, but otherwise everything appeared to be normal. On my first visit I gave ergotinin hypodermically, and prescribed calcium lactate in 10

grain doses to be taken alternately every three hours with a mixture containing liquid extracts of ergot, hydrastis, hamamelis, and *asok*,—(*Saruca indica*, Linn., a drug highly valued by Hindu physicians in uterine affections and especially in menorrhagia). This was continued for two days with no improvement, when injections of B. W. and Co.'s Tabloid Ergotoxine were added, without improvement. Adrenalin and pituitrin were next tried without benefit, and also emetine, as advocated by Monro in cases of hæmaturia (*Practitioner*, September 1918). The patient's condition was now serious; she was blanched, with a quick pulse of low tension and too ill to be removed to Calcutta for treatment.

Having read of "Hæmoplastin" (Parke Davis & Co.), in their "Therapeutic Notes," I tried a first dose of 2 c.c. subcutaneously with some diffidence. Improvement was immediate; especially after the second dose, whilst all hæmorrhage stopped after a third dose. A fourth dose of 2 c.c. was given; i.e., 8 c.c. in all, one such dose daily for four days. The patient made a complete recovery subsequently on a course of treatment with iron and strychnine, and to-day, more than a year later, is in excellent health.

A second interesting case was one of internal hæmorrhoids with a marked familial history. The patient's father died from the effects of hæmorrhage from piles at an advanced age, whilst a brother succumbed from the same cause after some years of suffering. A second brother died of sequelæ following hæmorrhage from piles in Calcutta some time previously. The patient was aged about 35 years and had been suffering from hæmorrhoids for 4 or 5 years. Bleeding was more or less intermittent, and his condition was bad. I advised him to go to Calcutta for operation, but he stated that he had already been advised in Calcutta that this was inadvisable. He was thoroughly alarmed and expected a fatal issue. Hæmoplastin was employed, both subcutaneously and locally; four injections, each of 2 c.c., being given hypodermically in four days. The patient is at present in good health and free from hæmorrhage.

I am aware that two isolated cases do not prove much; but the possible value of hæmoplastin in the treatment of cases of obstinate hæmorrhage seems well worth further investigation and trial.

TWO CASES OF TETANUS TREATED BY INJECTIONS OF MAGNESIUM SULPHATE AND CARBOLIC ACID.

By P. D. SAMUEL, L.C.P.S.,
C. B. M. Dispensary, Parlakimedi.

IN the *Indian Medical Gazette* for June 1923, p. 263, I advocated the treatment of tetanus by

injections of 15 m. of a 1 per cent. solution of carbolic acid, together with a routine mixture by the mouth. In the *Journal of Medical Missions in India* for April 1923, I came across an interesting article by Dr. Caleb Davies on the therapeutical uses of magnesium sulphate, in which he advocated its use as a nerve depressant in the treatment of tetanus, chorea, eclampsia, and as an adjuvant in anæsthesia.

In the following two cases of tetanus subsequently treated by me, no antitoxin was used, whilst the routine mixture previously suggested could not be made up, owing to the lack of certain of its ingredients in the dispensary.

Case 1.—Katcharijito, Pano by caste, male, aged 8 years, was brought to the dispensary by his parents on the 20th August, 1923. On admission he was unable to open his mouth fully, found difficulty in swallowing, and had occasional convulsions. A slight injury was present on the head a little above the temporal region. His speech was not clear and he was restless at nights.

Treatment.—(a) Daily injections were given of 25 minims of a 25 per cent. solution of magnesium sulphate in the morning, and of 15 minims of a 1 per cent. solution of carbolic acid in the evenings.

(b) A mixture containing 10 grs. of sodium bromide, and one drachm of magnesium sulphate was given four times a day until he left hospital.

The symptoms gradually decreased during his first week in hospital, and he could open his mouth and take liquid diet. At the end of the second week he could take rice, and at the end of the third he could walk and sing. He was discharged cured on September 14th.

Case 2.—Pakiru, Pariah by caste, male, aged 7 years, was admitted to hospital on the 5th March, 1924 for treatment of an ulcer over the external canthus of the left eye, the result of a ruptured boil. The customary antiseptic dressings were employed.

On the 6th March the patient shewed slight paresis. His mouth was slightly turned to the right side, and his speech difficult. Owing to the situation of the ulcer, the case was taken for one of facial paralysis.

The ulcer commenced to heal, but the symptoms became aggravated, and on the 10th March clonic convulsions appeared, about 8 to 10 a day, increasing in number during the night. Sodium bromide in 10 grain doses t.d.s. was given, but without effect.

The next day the jaw was entirely locked, especially on the left side, permitting the passage in of food only through a small aperture on the right.

Injections of magnesium sulphate and of carbolic acid in the same doses as in Case 1, were now given, together with 10 grains of sodium bromide b.d.

By the 13th, the number of convulsions was reduced to 2 or 3 a day, but he had had no sleep. On the 16th he was better, but still unable to take in food by the mouth, and still on a liquid diet. On the 19th he slept, sleep being disturbed by two mild attacks. He could also partially open the mouth and take a little rice.

On the 21st, the injections were discontinued, and a mixture containing 10 grains of sodium bromide and one drachm of magnesium sulphate given orally t.d.s. On the 31st March he was discharged cured.

It would appear from the cases cited, and from these two further cases, that in mofussil practice, treatment by such injections may cure cases without recourse to the costly antitoxin, or where such antitoxin is not available.

My thanks are due to Dr. J. H. West, M.D., C.M., for advice and assistance.

Indian Medical Gazette.

APRIL.

THE MEDICAL RESEARCH COUNCIL.

WE in India, are specially interested in the working of the Medical Research Council of the United Kingdom as it plays the same part as our Indian Research Fund Association.

The funds of the Medical Research Council are derived from the Imperial Parliament, which sets apart a small proportion of the income derived from the working of the Insurance Act. Although the proportion of the imperial revenues which are allotted to research is small, it is vastly important that the principle has been established that there should be a definite reservation for research. Experience has shown that the due development of agriculture, industries and medical knowledge depends on the work of the investigator, and already the results which have been attained are such that any change in policy in the future must be in the direction of allotting a larger proportion of the revenue for research.

The work done by the Medical Research Council is directed partly to the solution of definite problems and partly to the promotion of medical knowledge in general, and it is most encouraging to find that, when a specific problem is directly attacked, medical knowledge in general has been found to benefit, and on the other hand each addition to medical knowledge helps in the solution of specific disease problems.

Although the scheme has been in active operation only for a short time, the fruits of research have been so great that they are already of great importance and are becoming more valuable every year.

The greater proportion of the available funds has been spent on subsidising existing educational bodies, either in the form of subsidies to persons who have proved their capacity for research work or in the form of grants for the promotion of special investigations; no less than £80,000 have been spent in this way last year. Rather more than half this amount is spent on the National Institute of Medical Research and its associated field laboratories. The chief problems which have been dealt with by the National Institute are those of physiology, pharmacology and biochemistry. But the work which has been carried out is far from being academic in nature, it has more or less direct bearing on the problems of disease and inefficiency.

The conspicuous success of the Research Council has been due to the policy of making the greatest possible use of existing institution and to the broad-minded administration of Sir Walter Fletcher.

The Indian Research Fund Association was established on the same lines and has carried on work of vast importance to India, but owing to the unfortunate curtailment of its funds in consequence of the report of the Inchcape Retrenchment Committee, its activities have been sadly crippled.

The damage which has been done is not confined to the interruption of valuable research work, almost more serious is the harm which has been done by the blow which was struck at recruitment of research workers.

If research is only to be subsidised in years of prosperity and is liable to be shut down when a cry for retrenchment is raised, it is impossible to adopt a settled policy or to attract suitable men to the research cadre.

We cannot too strongly emphasise the necessity of adopting a consistent policy, such as has so wisely been adopted by the British Government in England, if medical research is to continue to bear fruit of increasing value to this country.

It is understood that the meagre grant to the Indian Research Fund Association is to be restored, at least in part. There must be some guarantee that this grant will not be at the mercy of the finance department or of the party politician.

If a settled grant be given which will bear some proportion to the total revenue of Government, the next important business is to work out a policy for the most effective utilisation of the income of the Association.

In view of the fact that a statesmanlike policy was adopted by the Association at the time of its inauguration by men like Sir Harcourt Butler and the late Sir Pardey Lukis, and in view of the great success which has attended the pursuit of a similar policy by the Medical Research Council in England, it is reasonable to expect that the same lines will be followed by the Research Fund Association with the funds which are now being placed at its disposal.

The first thing to be done is to make the fullest use of the men who are available and of the existing institutions. We have seen the abandonment of the important work of Lieutenant-Colonel R. McCarrison because of the need for retrenchment; we have seen the great nursery for research workers of the future, the Calcutta School of Tropical Medicine, compelled to carry on without an expert helminthologist, without a biochemist and without a museum of hygiene; we have seen the Bombay School of Tropical Medicine still-born because of lack of funds; we have seen other research laboratories hampered for

want of workers and recruits. The removal of these defects will doubtless be the first object of the Research Fund Association in any enlarged programme.

The encouragement of young men who show aptitude for research will rank high in the programme, and so will the provision of workers for the attack on the many disease problems which exist in India.

It is certain that the available funds will yield a far greater return if the greatest use be made of existing institutions, and if the available money be spent on men instead of on a brick and mortar policy such as led to the undoing of the Research Fund Association in the past.

The best interests of the country will be served by the employment of the best available men, and by the building up of a band of competent research workers. The men who are employed should be located at the places in which they can do the most effective work, whether this be at existing research centres or in the field.

In the words of Sir Harcourt Butler, "we must think imperially," and we should go a step further and act imperially.

SUB-ASSISTANT SURGEONS' ALLOWANCES IN BENGAL.

As a result of the recommendations of the Retrenchment Committee in Bengal, certain allowances hitherto enjoyed by the Sub-Assistant Surgeons have been abolished. These are (1) house-rent in the case of those posted to sub-divisional headquarters and (2) teaching, house-rent and medico-legal allowances in the case of those holding posts of demonstrators in the medical schools, and teachers of compounder classes where they exist.

The Sub-Assistant Surgeons submitted a representation to the Surgeon General for transmission to Government in which they set forth their grievances owing to the abolition of their allowances and prayed for their restoration. One of the grounds urged was that when the time scale of pay was introduced in 1921 on the report of the Medical Services' Committee, assurance was given in Government Resolution No. 1998, dated the 22nd July, 1921, that the various allowances hitherto enjoyed by the Sub-Assistant Surgeons would be continued to be drawn by them in addition to the new scale of pay.

The Government have replied to the representation regretting their inability to revise the orders, as they do not consider that the Sub-Assistant Surgeons have any grievance, because the orders about house-rent and medico-legal allowances do not affect the Sub-Assistant Surgeons now in

service, and those relating to teaching allowances are not applicable to the officers holding teaching appointments at the time the orders were issued.

All these cases may fairly be considered in the light of the laws of supply and demand. Government are quite within their rights in offering lower rates of pay to future incumbents, but it is doubtful whether the slight saving which will be effected will be a true economy. The prospects of teachers and demonstrators are hardly enough to attract the best men; if the pay is reduced, there will be still greater difficulty in recruiting for the teaching staff of the medical schools.

SPECIAL ARTICLES.

THE INSECT MENACE.

By F. P. MACKIE, O.B.E., M.D., F.R.C.P., F.R.C.P.S.,
LIEUT.-COLONEL, I.M.S.,

Director, Bombay Bacteriological Laboratory, Parel.

(Being the Presidential Address to the Medical Research Section of the Indian Science Congress, Benares, January 1925.)

BEFORE I begin my address, I wish to express the high sense of honour I feel at having been invited to the occupation of this Presidential Chair and being thereby privileged to follow in the steps of so many distinguished men.

For nearly twenty years in the Medical Research Department my principal interest has been in the relationship of insects to the transmission of disease, having devoted successive periods of time to fleas and plague, bugs and lice and relapsing fever, mosquitoes and malaria, tse-tse flies and sleeping sickness, and to the insect side of the kala-azar problem, so that I decided to take as my theme some reflections on this profoundly important aspect of tropical pathology.

If these remarks serve to draw attention to the grave problems which the people of India in particular, and of the tropics in general have to contend with, I shall feel that they have not been in vain.

I often think as I read the statistics which are published in the daily papers from time to time recording the number of persons killed every year in India by tigers, panthers and venomous snakes, how much more striking it would be if figures were published showing the number of persons killed every year by the bites of insects.

Tigers and snakes are unpleasant creatures to meet and spectacular in their actions, but the number of lives they claim is a drop in the ocean compared with the vast army of persons who die every year in India from the bites of insects.

In estimating the number of deaths caused by insects we may consider two classes of disease, firstly those which are conveyed by insects and by insects alone, and secondly those in the transmission of which insects undoubtedly play an important or contributory part.

In the first class we place malaria, plague, relapsing fever, guinea-worm disease, filariasis, dengue and sand-fly fevers, and almost certainly kala-azar. In the second class come a number of diseases, particularly those of intestinal origin, such as cholera, enteric fevers, the dysenteries and infantile diarrhoea, to name only the more important.

If we turn to the reports of the Public Health Commissioner for India, we read that in the last two years

for which statistics are available, the number of deaths in British India alone was as follows:—

Fevers (the large majority of which are malaria).

In 1921	4,761,000
In 1922	3,689,000
Plague.			
In 1921	69,000
In 1922	77,000

This means that during the years 1921 and 1922, no less than eight and a half million persons died from insect bites in British India alone.

In the first six months of the year just passed (1924), 200,000 persons died from plague in the Punjab, whilst over ten millions of lives have been sacrificed to plague since the epidemic began about twenty years ago.

Now take those diseases where insects take some part in the transmission:—

The deaths from cholera are given as follows:—

In 1921	450,000
In 1922	121,000
whilst deaths from dysentery were:—			
In 1921	229,000
In 1922	177,800

During the two years nearly one million persons died from these diseases.

All these figures represent deaths, but how many persons suffer from ill health as a result of repeated attacks of insect-borne disease? Their number is incalculable.

In the same report we read that Dr. Bentley has calculated that every year in the province of Bengal alone there are 28,300,000 persons suffering from malaria, and that if his calculations are applied to the whole of British India, there are not far short of one hundred million cases of malarial fever in any one year.

If we were to apply these methods of calculation to all the diseases known to have been caused by insects, and add to this a proportion of the second class of diseases in which insects play a contributory part, we shall see that the amount of disease, invalidism and death which occurs every year in India from the bites of insects is enough to stagger humanity.

It is evident from this that India has to bear an enormous economic burden from the incidence of preventable disease which is sufficient to prevent her rising to the position of importance to which her huge population and great resources entitle her. This aspect of the problem was most ably dealt with by the last President of this section, Lieutenant-Colonel S. R. Christophers, C.I.E., I.M.S., in his address at Bangalore last year when he took as his theme, "What disease costs India."

Let us now proceed to examine in greater detail this problem of noxious insects and their depredations.

The antiquity of insects.

The first thing which strikes one about insects is their great antiquity, and in consequence the perfection of their adaptability to environment.

Man is comparatively speaking a new-comer to the earth. He has only reached recognisable human characters for about half a million years or at most a million, for he only appears during the latest geological epoch, the Quaternary period, or at the earliest during the Pliocene period of the tertiary and for this a million years is a generous estimate.

But as far back as there are records of life on this globe, in the Cambrian rocks of the Primary or Palaeozoic period; many of the present classes of insects were represented, and throughout all those ages they have been evolving, multiplying in type, adapting themselves to an infinite diversity of conditions and later becoming fixed and immutable in their varying life processes to a degree which contrasts with the relatively fluid and plastic condition of the species of higher animals which have appeared so much later.

When as yet only the simplest aquatic Metazoa and worms existed on the earth, even then the primitive

forms of insects, the ancestors of those which we see to-day, began to be evolved. That period may be roughly taken as one hundred million years ago, and in that vast period the forces of evolution have produced the wonderful mechanism and the inexorable regularity of structure and function which we see in the insects to-day.

If we cast back in imagination to those times, we can imagine the brooding darkness of primeval seas made visible by the phosphorescent glow of myriads of marine crustaceans, whilst a few million years later when the only terrestrial inhabitants were gigantic reptiles more horrible than a madman's dream, their nocturnal browsings amongst the primitive palm groves were lit by the twinkling flash of fire-flies, probably in no wit different to those which we admire to-day in swamps and bamboo brakes.

As for the future of insects it has been humorously said, I think by H. G. Wells, that in the ages to come, when the last man sits shivering on the equator wrapped in furs and trying in vain to obtain warmth from the dying rays of a burnt out sun, there will be a fly buzzing round and waiting for an opportunity to settle on his nose.

The lesson to be learnt from these reflections is that insects have been here almost from the very beginning of time and will remain as long as any life is possible, so that we must make the best of them and learn when we may attack them to their greatest disadvantage. For these reasons the minute study of the life history of insects is one of the most profoundly important branches of tropical pathology, for it is only by taking every advantage which is offered that man may hope to defeat these, the greatest of all his enemies.

The marvellous qualities of organisation and perfect adaptation to environment are best seen in the so-called social insects, such as ants and bees. The social systems of these insects are so wonderfully ordered that they may be taken as models of what human society may one day attain to, indeed there are some who consider that we human beings cannot reach anything more perfect than the system already evolved by ants and bees.

They have their queen whose royal prerogative it is to lay vast numbers of eggs for the nurseries; the resulting horde of workers sterilised so that their capacities for work shall not be deflected by the lure of sex; their soldiers, scavengers, their flocks and herds and their small band of lazy but necessary males whose sole ambition is to take part in a nuptial flight, the victor's reward being total emasculation and to be hurled Icarus-like to the earth beneath. This is a gloomy outlook indeed for our sex—this state of rampant matriarchy in which the pleasure loving male shall be relegated to a position of permanent inferiority.

It is difficult to believe that this highly organised social system is not the result of conscious and intelligent direction, but it would be a mistake to suppose that this is so: the only directing influence in a hive is instinct, which is the summation of hereditary experiences, and there is no cause or justification for calling in reason to explain any of the complicated reflex actions of insects.

These facts help us in the destruction of insects because we know that no glimmer of intelligence will interrupt the preordained march of habit, as for instance in swarms of locusts which can be depended upon to advance unswervingly into fire or water rather than to deflect one hair's breadth from the drive of instinct.

The development of the parasitic habit of insects.

It is of great interest to ponder over the development of the parasitic habit and what it has led to.

This probably was an early development, for it must have been discovered that the easiest way to avoid the intense struggle for life in the primeval slime was for an insect to attach itself to some reptilian monster and to take cover under the overhanging shields with which it was armoured. It is probable that the ancestors of

Hyalomma and Amblyomma ticks infested the primitive reptiles, just as they do their smaller descendants to-day—firstly, for security and later as they developed the blood sucking habit, for food, and so they developed into true parasites.

When the birds came, there were other types of insect parasites evolved; first those that visited their hosts to feed on scraps of feathers or scurf and were free fliers. Later some learned to suck blood and found that flight was unnecessary as they could pass from one bird to another at roosting time, and so their power of flight was lost.

By some such process the Mallophaga or bird lice arose, once free fliers but in whom now the wings are atrophied and suppressed into mere vestiges.

The Nycteribidae of bats and the Hippoboscidae of domestic animals are probably undergoing this change to-day, as their flight has become restricted to a few feet around their hosts. It is probable that these lice of birds are amongst the most archaic of parasites, and as their environment has undergone so little change for ages they have become highly specialised and are now specific each for his own species of bird and quite incapable of living on an allied species of host. This fact has been well exemplified by an attempt which was made to connect genera of birds living in places as far apart as Australia and Patagonia by the fact that they were infected with identical species of Mallophaga.

The identification of the avian species was held valid on these grounds, although the geographical separation took place as long ago as the Jurassic period. At that period of the world's history a man (had he existed) could have walked dry-shod from South America across a land bridge to South Africa and thence through Madagascar and up to India and thence down to Australia by the great Asia-antipodean land bridge of which the only remains now above water are the islands of the East Indies.

This shows that ages which sufficed for a complete evolutionary divergence of birds were but a short time in the ancestral history of their insect parasites.

Of the insects which attack man some are entirely specific and therefore of great antiquity as parasites; such are the mites and the lice. These may have accompanied man in his upward climb from a simian or tarsian ancestry.

Mosquitoes have probably acquired the blood sucking habit more recently, for they are not specific to man but bite other animals, they are not complete parasites as for the greater part of their life they lead a saprophytic and aquatic existence. The vast majority of mosquitoes live and die without an opportunity of sucking human blood. On the other hand they have had a sufficiently long experience to become the final host of a highly specialised human blood parasite.

Tse-tse flies are probably still more new to the rôle of human blood-suckers, and this may in part explain the fulminating nature of the epidemics they transmit; their natural victims are the vast herds of animals which have roamed the plains of Africa since the tertiary period.

Fleas have developed strong predilections for their hosts, but are not entirely specific, whilst their disease transmitting powers do not bear the stamp of prolonged evolutionary experience. As for bugs they are not essentially but only casually human parasites and spend no part of their life history on his body. Either from lack of practice or from a benign disposition they do not appear to have taken up the evil habit of disease transmission, or at least this has not been proved against them.

House flies, Stomoxys and other muscids cannot be said to be human parasites at all, but are commensals or mess-mates which are apt to transmit certain diseases, generally bacterial, as a matter of incident in their life history. The bacteria undergo no essential stages of development in these insects, and we may call them "porters" rather than true "carriers" of disease.

To summarise what we have been saying, we may consider there to be several classes of disease carrying insects. Firstly, those which are specific to man and which spend the whole of their life history on his body. Such are the mites and the lice, and these from their habits should be capable of easy extermination. Secondly, those like mosquitoes, tse-tse flies, ticks and fleas, which are carriers of specific parasites and though living in part a saprophytic existence probably require blood for their full sexual development. Thirdly, those which are casual or occasional parasites such as flies and even rat fleas which for man are only incidental or accidental disease carriers.

The transmission of disease by insects.

If we examine creatures lower in the scale of life than man and of much greater antiquity, such as reptiles and amphibians, we shall find that they are all infested with intestinal protozoa and the large majority also carry blood protozoa such as trypanosomes, trypanoplasms and hemogregarines, all of which appear to be quite harmless to their hosts.

This probably represents the result of a struggle which at some earlier period was carried on between the parasite and the host, but which has now ended peacefully in a compromise between the two as a state of commensalism or harmless parasitism. If we could look back to the time when these blood parasites first established themselves in their reptilian hosts, we should find that epidemics of trypanosomiasis for instance swept through the reptilian world, just as they now sweep through human and animal populations in Africa to-day.

It may be that such epidemics were the cause of the extinction of the great prehistoric reptiles which roamed the world before the dawn of history, and that these succumbed to an infection which in their lesser brethren which survive to-day resulted in the state of equilibrium which now exists between reptiles and amphibians and their blood parasites.

The same argument may be applied to parasitic diseases of higher animals. Take rats for instance: they are infected with a trypanosome which has habituated itself long enough to become specific for the rat and long enough to have almost succeeded in establishing itself as a harmless parasite. In places where this infection is endemic, the young rats suffer from an infantile disease which is probably rarely lethal and to which the adult rats are immune carriers of the infection.

This is paralleled by the infantile diseases to which our children are liable, such as measles and chicken-pox, which at some earlier period were doubtless mortal diseases, but now by reason of hereditary or racial immunity have become comparatively innocuous. This is exemplified by the well-known fact that when measles was introduced into the Sandwich Islands, it gave rise amongst the non-immune natives to a virulent epidemic with a mortality comparable with that of bubonic plague.

The state of equilibrium referred to is as advantageous to the parasite as to its host, for it is obvious that if the disease produced is sufficiently deadly to destroy the host, it will result also in the death of all the parasites which are dependent on that host for their sustenance. The result of this is that the parasite reduces its toxicity, and the host develops some degree of tolerance, so that ultimately the two lie down together like the lion and the lamb, whose charming communism is so optimistically foreshadowed in Isaiah.

If we apply these principles to insect-borne diseases, we may believe that when these diseases were first evolved they were severe and assumed epidemic proportions, whereas the longer they exist the less severe they become.

So for instance in course of time, provided the human race survives its ravages, malaria will set up a condition of harmless equilibrium and the parasites flourish in its human host with satisfaction to themselves and without harm to their host. Such a happy

state of affairs probably exists already in bat and monkey malaria and in some plasmodial and trypanosome disease of wild animals.

Even in human malaria there are endemic centres of low toxicity, low that is to the endemic population, and this exists in parts of Central Africa and of India. In these communities the children all become infected and take malaria as an infantile disease, whilst the adults are all carriers and themselves show no sign of disease. The arrival of non-immunes in such a community results in intense and often fatal infections amongst the new comers.

As to exactly how these micro-parasites came to establish themselves in human beings, is a matter of conjecture. The most generally accepted hypothesis is that sporozoan flagellates and other blood parasites were originally harmless inhabitants of insects and evolved the habit of transmission from one host to the other at some later period of development. Many, if not most, insects harbour intestinal protozoa, and as they developed the blood-sucking habit their parasites accustomed themselves to the rich and easily assimilable food which blood provides. It was then found that when these protozoa were introduced into the blood stream of their vertebrate hosts they were able to establish themselves there and so set up an "alternation of generations."

They may have found their way to the blood stream by some simple method, as through a surface abrasion or through the puncture made by the insect in biting such as is seen in plague, relapsing and tick fevers.

An alternative method of introduction is by a soiled proboscis, where an insect bites a diseased animal and forthwith bites a healthy one and so carries infection from the one to the other, just as one might do with a dirty hypodermic needle. It was considered at one time that human sleeping sickness was carried in that way, and we still believe that this is the method by which tabanids and *Stomoxys* transmit surra of horses and camels.

A further adaptation is that met with in some trypanosome diseases of animals, e.g., *T. vivax* where simple multiplication of the parasites goes on in the lumen of the insect proboscis and is passed on after a short period of development. This we may liken to the multiplication of germs in the lumen of a dirty hypodermic needle. The final stage of complexity is represented by those cases in which the protozoon finds its way into the intestinal canal of the insect and there undergoes a cycle of development, and, after a period of non-infectivity, finds its way into the salivary glands and thence in a highly infective state into the blood stream of another vertebrate host.

The most typical example of this is of course the malarial parasite in the mosquito, whilst the development of the trypanosome of human sleeping sickness in the tse-tse fly is a scarcely less perfect instance.

This crescendo of complexity is in itself suggestive of the origin of the blood protozoa from the harmless intestinal commensals of insects. It has recently been maintained by well known protozoologists that the intestinal flagellates, even of non-blood sucking insects, can give rise to a Leishmania-like disease in laboratory animals, and that, for instance, the parasites of a water flea will give rise to disease and death when injected into a mouse, two creatures which never come into contact with one another in Nature.

Although their experiments seem to be well grounded, it is only fair to state that they have met with opposition from and refutation by those who sought to confirm them, and indeed such astonishing results can only be credited with difficulty.

The alternative hypothesis of the evolution of the parasitic habit is that the tissue parasites of vertebrates originated from their own intestinal canals and that they were originally mildly toxic or non-pathogenic inhabitants of the vertebrate alimentary canal.

We know this holds for one human parasite, the amœba of dysentery which being essentially an intestinal organism does find its way into the intestinal wall and then into the liver or brain setting up disease and death.

Certain biflagellate organisms such as *Trypanoplasma* are closely related to intestinal organisms like trichomonads, and it seems probable that these may occasionally pass from the gut into the blood stream of amphibians and may subsequently have adapted themselves to the insect vector and so have ensured transmission from one host to another.

We may regard both these hypothesis to be probable, though we believe that the majority of blood parasites of the higher vertebrates have their origin in the intestinal canal of insects.

Insects which are concerned in the transmission of disease.

We will now make a short review of the arthropod carriers and say something of the diseases they transmit. Our time is much too short to deal in detail with this wide and important subject, but what follows may serve to refresh your memory and to bring home to you what is the object of this address, namely, to emphasise the menace to man and to the domestic animals which is brought about by insect carriers.

The two main divisions of the *Arthropoda* or jointed limbed animals are the *Arachnoidea* which include the ticks, mites and spiders—all eight legged,—and the *Hexapoda* including the lice, bugs, fleas, mosquitoes and flies which are all six legged in their mature forms.

The mites which interest us are the *Acarinae* such as the harvest mites, and the large group of the *Sarcoptes* which includes the human itch mite, and the many forms of itch and mange and scab mites which attack man or his domestic animals. Harvest mites are tiny creatures which live in vegetation and at certain seasons burrow into the skin of man, giving rise to much urticaria and irritation. One species, the Kedani mite, gives rise to a definite febrile condition called Japanese river fever. Mites are common in some parts of India, but beyond the irritation they cause are not known to give rise to any specific disease.

The itch mites are very widespread and cause much trouble, especially to poor and uncleanly persons, by the production of the disease known as itch. Mange and scab amongst domestic animals are ubiquitous and give rise to exceedingly intractable forms of skin disease. The mites are specific for the hosts they infect and this suggests that they have acquired the parasitic habit at some very remote period of time.

Ticks are creatures remarkable for their longevity, their powers of resistance to adverse influences, and their fecundity. Adults will live unfed for one or even two years, and will resist the action of chemicals and disinfectants which will immediately destroy most other forms of insect life. They pass through a series of moults as they grow from minute larvae to sexually mature adults, and at each feed they fall to the ground and after moulting have to find the right host if development is to be continued. The patience and tenacity of these creatures is remarkable, and they may be seen on a blade of grass or a twig waiting for weeks or months for the right species of animal to pass by. Their immense fecundity is thus explained, for like all living creatures they are prolific in direct proportion to their chances of destruction in an immature stage. The female tick lays anything up to five thousand eggs at a sitting and only a few of these have any chance of attaining maturity. Ticks have specialised in the transmission of a particular genus of blood parasites—the *Piroplasmata*, though perhaps only one of these causes disease in man (Oroya fever). *Piroplasmata*, as far as their life histories have been worked out, are all carried by ticks, and the damage done to domestic stock by Texas fever, red water fever, and similar diseases of cattle is enormous; whilst horses, sheep,

goats and dogs have each their specific *Piroplasma* diseases which are in every case carried by ticks.

The other great family of ticks—the *Argasidae*—transmit a totally different kind of blood parasite—the spirochaetes.

African relapsing fever of man is transmitted by a tick of this family (*Ornithodoros moubata*), whilst epidemics of spirochaete diseases of birds, fowls, geese, and ducks are caused by the ravages of *Argas persicus*, the fowl tick.

A human typhus-like disease met with in parts of the Himalayas is believed to be carried by ticks, and relapsing fever in Persia is said to be caused by species of *Ornithodoros*, but these suspicions remain to be proved.

We pass on now to the *Hexopoda*, the true insects.

Those which concern us as human parasites amongst the *Hemiptera* are the *Pediculidae* or lice, *Cimicidae* or bugs, and the reduvid bugs of the genus *Conorhinus*.

Lice.—Blood-sucking lice are very dangerous parasites of man, for three severe and often fatal diseases are transmitted by them and probably by them alone. The first evidence incriminating the louse as a carrier of specific disease in man was produced in India in 1907 when it was shown that Asiatic relapsing fever was transmitted by this insect. This was verified in Northern Africa and in European countries and this insect is now held to be the chief if not the only cause of the spread of relapsing fever in nearly every part of the world. Shortly after this discovery, typhus fever, a disease closely resembling relapsing fever, was shown to be similarly transmitted. The widespread and fatal epidemics of these two diseases, particularly in Russia and Eastern Europe during and since the war, reveal the deadly potentialities of lice and at the same time have shown the way to prevention by the comparatively simple method of delousing the susceptible community.

A third disease is also louse-borne—trench fever—which gave rise to a large amount of disease and invalidity amongst the soldiers in the trenches during the great war. The cause of this disease is not entirely settled, but is probably due to a very minute polymorphic organism belonging to the genus *Rickettsia*.

Bugs.—These unpleasant insects are too well known to need any description. They have been suspected of transmitting several diseases such as kala-azar, leprosy, relapsing fever, plague, infantile paralysis, but it cannot be said that the case has been proven against them in respect of any of these diseases. Apart from their disease carrying possibilities they are an intolerable nuisance and may produce a condition of ill-health in their victims by disturbing sleep and even by producing anaemia by their voracious blood sucking. The *Conorhinus* bug (*C. megistus*) is a large blood-sucking insect which in South America transmits a human trypanosome (*T. Cruzi*). An Indian species, *C. rubrofasciatus*, has been suggested as a possible carrier of Indian kala-azar. It is found in Madras and in Assam—both endemic areas of the disease,—and lives in native huts and occasionally bites men. No further evidence of its transmissive power exists.

Passing on to the large order of *Diptera*, we find the family of *Siphonoptera* which includes the fleas. These insects are particularly notorious in that they transmit plague and their mode of action presents some peculiar features. All the diseases we have hitherto been considering are caused by protozoa, whereas plague is a bacterial disease, and with tularaemia is one of the few bacterial diseases carried by the bites of insects. Again plague is primarily a disease of rats and is only incidentally, almost accidentally, a disease of man.

The plague bacillus multiplies enormously in the alimentary canal of the flea and to such an extent in some insects that a blocking at the entrance of the stomach occurs and in such fleas regurgitation of highly infected material takes place into the puncture, and in this way

the plague bacillus finds its way into the circulation of man.

Fleas are credited with the transmission of relapsing fever, leprosy, etc., but this is unproven. The rat flea, however, is responsible for the transmission of the trypanosome disease of rats, (*T. Lewis*).

The *Sarcophyllidae* or jiggers are burrowing fleas which infest the skin of the feet and set up severe septic complications; they are not found in Asia.

The Culicidae or mosquitoes.

A true insect carrier or vector is one in which the specific parasite undergoes a necessary part of its life-history, i.e., part of its alternation of generations, in the insect host. The most perfect example of this is the development of the malarial parasite in the body of certain *Anopheles* mosquitoes. This is true parasitism and one must suppose that but for the presence of susceptible human hosts and the appropriate insect carrier, the parasite of malaria would become extinct. It also appears that a meal of blood is necessary to the female mosquito for the maturation of her eggs.

It is interesting to note that of all mosquitoes only the *Anopheles* have learned the evil habit of malarial transmission, and of all the species of *Anopheles* only about a score the world over have been proved to be carriers of malaria in nature. In some others it has been found possible to infect them by laboratory experiment, though in Nature this does not happen. In others, development goes a certain distance and then withers and dies, whilst in the majority of *Anopheles* the malarial parasite does not develop at all. What these profound differences depend on, we know not, but it shows how subtle must be the interaction between parasite and host and it offers hope that this incompatibility may be brought about artificially when once we know its cause.

There are two other important genera of mosquitoes which carry disease but are apparently quite incapable of transmitting malaria. A small worm parasite (*Filaria Bancrofti*), the cause of filariasis and of its sequela elephantiasis, is transmitted by certain species of *Culex*, and dengue is also believed to be carried in the same way.

Yellow fever, the scourge of Central and South America, is transmitted by yet another kind of mosquito, the *Stegomyia*. The stamping out of yellow fever in these countries, where it was epidemic, is one of the greatest triumphs of modern preventive medicine and shows what can be done to eradicate mosquito-borne disease if only expert knowledge, organisation, energy and money are in league together.

We see that mosquitoes are able to transmit four totally distinct diseases:—

- (a) Malaria, due to a blood sporozoon.
- (b) Filariasis, due to a blood nematode worm.
- (c) Yellow fever, due to a blood spirochaete.
- (d) Dengue, a disease of unknown causation.

The family *Simuliidae* includes the sandflies which are concerned in the transmission of the short fever of that name. This disease is never fatal, but gives rise to a great deal of sickness and temporary invalidity in countries like Iraq and in the Punjab where sandflies are prevalent.

Sandflies of the genus *Phlebotomus* are suspected of being concerned in the transmission of parasites of the herpetomonad or Leishmania type.

Flagellates of this nature were found by Wenyon in 1912 in Aleppo, an endemic centre of oriental sore, and in 1914 by me in an endemic centre of kala-azar in Assam.

In 1921 the brothers Sergent and others incriminated species of *Phlebotomus* as transmitters of oriental sore in Tunis, and just lately the Calcutta workers and the Assam Kala-azar Commission have brought evidence to suggest that these insects may be concerned in the spread of kala-azar.

It appears probable that the flagellates found by Wenyon and by me were in reality developmental

forms of the *Leishmania* parasites rather than natural flagellates which they were provisionally considered to be. Papers are being contributed to this discussion bearing on this interesting problem, and further developments are awaited with great interest.

The Muscid flies include many species which are or may be noxious to man. Such are the common house fly, the stable fly (*Stomoxys*), the various kinds of "blue bottles" which lay eggs in dead or damaged human tissues, the *Tabanids* or gadflies, *Hæmatopota* and *Chrysops*, and most important of all—the tse-tse flies.

The common house fly on account of its dirty habits is an undoubted transmitter of disease, for the germs of enteric fever, dysentery, cholera and other intestinal diseases have been found in or upon it. An experimenter in America found that out of 414 house flies an average number of one and quarter million bacteria mostly of fecal origin were found on the outside of the flies. The fouling of milk and other articles of food is thus easily explained. There are various species of "blue bottle" flies,—*Lucilia*, *Sarcophaga*, *Oestrída*, and others which lay eggs in diseased human tissues. Larvæ or maggots are produced and these live on the dead matters of the wound and give rise to much suffering and mutilation. It is interesting to note that the larva itself of one of these flies has developed the blood-sucking habit. This is the Congo floor maggot—the larva of *Auchmeromyia luteola*. This creature lives in cracks in the floor of native huts in Central Africa and emerges at night to visit sleeping human beings. It burrows under the skin, takes its fill of blood and returns again to the ground to digest its meal. It has taken to nocturnal habits and acts almost exactly like the human tick (*Ornithodoros*) with which it lives side by side, an interesting example of convergent evolution in two totally distinct types of creatures.

Of the blood-sucking muscids, the tabanids and *Hæmatopota* are carriers of disease amongst domestic stock both in India (Surra) and probably also in Africa.

One species of the genus *Chrysops* transmits a worm parasite in human beings—the filarial parasite *Loa-loa*.

Tse-tse flies.

Flies of the genus *Glossina* or tse-tse flies are responsible for an enormous amount of disease in tropical Africa due to trypanosome infection.

Two species of trypanosomes affect man, giving rise to sleeping sickness of the Congo and Uganda type or of the Rhodesian type. In addition to these there is an immense amount of damage to domestic stock, cattle, horses, sheep, by trypanosomes of different species which are all transmitted by tse-tse flies. The interesting point about these diseases is that the infection exists in the wild game which live in these countries from which the tse-tse flies get their infection and which represent natural reservoirs. This is an example of what we were saying before about racial and hereditary immunity; the antelopes and other wild game are immune to these diseases, which assume epidemic form in man and his domestic animals in which no such immunity exists.

I well remember an impressive example of this which occurred in Uganda. An antelope was caught on the lake shore and kept in captivity for many months in a perfectly healthy state. Its blood was examined daily for months, but no trypanosomes were ever seen. Batches of newly bred tse-tse flies were fed on the antelope and after a suitable interval were fed on a susceptible animal, a monkey. Every batch of flies fed on the antelope were shown to be infected with sleeping sickness, the antelope therefore being a healthy carrier or reservoir of sleeping sickness. The tse-tse fly being the natural vector had the power, so to say, of filtering out of the blood the infective trypanosome which was so scarce as never to be seen with the microscope.

I have now said enough to impress upon you the importance of the study of insect life and shown you how

the well-being of tropical communities will be affected by such studies.

If this were all it were important enough, but there is the added interest of the purely scientific side of such studies to emphasise the importance of the little things in life; for though they are small and frail and simple in construction, these insects carry within them the secrets of life, no less than do the large and more complex animals.

When one looking down a microscope sees an amoeba creeping out of dead matter and proceeding on its way in the exercise of its simple functions, one is reminded that this is the very life plasm which one sees in all its nakedness, this is the very fashion in which life emerged from chaos at the dawn of time, and that within this small creature are hidden the eternal mysteries of life and death.

Tennyson clothed this idea in poetic language when he wrote:—

"Flower in the crannied wall,
I pluck you out of the crannies,
I hold you here, root and all, in my hand,
Little flower—but if I could understand
What you are, root and all, and all in all,
I should know what God and man is."

The application of the knowledge to the prevention of disease.

Having now considered briefly some of the theoretical aspects of the problem of disease transmission by insects, it behoves one to say how our knowledge on the subject can be applied to the betterment of public health. We have seen from the statistics that insect-borne disease is an enormous burden on the financial, economic and social conditions of the Indian people, and you will agree that a policy of drift or an attitude of fatalism cannot be longer tolerated. India, like other Eastern countries, is awakening from her long slumber and this immense fatality from preventable diseases is one of the most important problems which she has to face.

Now that she is at the turning of the roads, it is of great importance that her steps be guided aright, and she must be shown how necessary it is to pay more attention to problems of public health. The unhealthiness of the tropics and sub-tropics is not a question of heat or humidity or such physical states, but is due almost entirely to the diseases which these conditions foster, so that if we rid India of these insect-borne diseases, we should go far to bring her mortality into line with that of temperate countries.

The first essential before we can make much advance is to convince our legislators, our officials, and, most important, the population at large, of the importance of preventive as compared with curative medicine.

Public opinion in most countries is entirely wrong in its estimate of the relative importance of these two aspects of medical science, though of recent years the more enlightened countries of the West are beginning to revise this estimate. The effect of curative medicine on public health is relatively trivial compared with that to be expected from a rational application of preventive medicine.

Yet the panacea for the high mortality in a district is to provide more hospitals or dispensaries, without pausing to consider whether disease will be reduced by so doing. Hospitals are of course quite essential and the personal treatment of the sick is taking and always will take a high place on grounds of humanity; but if we wish to reduce the mortality from epidemic or transmissible diseases, it will not be by building hospitals only, but by spending at least a part of the available money on preventive measures.

To expect to stamp out malaria by curing some of its victims is as unreasonable as to suppose that when one draws water from a spring one is thereby reducing the underground supply by which the spring is fed. Disease is welling up all around us, constantly or intermittently, the laws which govern its rise and fall are

almost unknown, but the treatment of it is ever necessary it may be, cannot be necessary for the more rational procedures of the sanitarian.

Most of the great discoveries of our science in the last century have been in prevention rather than cure. Take for instance, the prevention of small-pox by vaccination, the reduction of typhoid fevers by inoculation, the prophylaxis of tetanus by serum, the prevention of sepsis by Lister's discoveries, and even the prevention of pain by anesthetics.

I will go further and say "*transmissible diseases will never be abolished by curing, but only by preventing them.*" This truth finds popular expression in the saying, "Prevention is better than cure," a proverb that has lost the profundity of its truth by its very triteness.

The lowering of the death rate, especially of the infantile death rate, the increased expectation of life, and the general increase of healthiness which have been brought about during the last half century in the more civilised countries of the West, have been caused not so much by the success of curative medicine but almost entirely by the triumphs of prevention.

One of the most amazingly retrograde steps which has resulted from our recently acquired methods of legislation is the demand from one province after another for the abolition of Public Health Commissioners and the weakening of the services they control. That politicians should be found so short-sighted as to try to weaken the very organisation on which the whole health and future prosperity of India depends, causes one to lose faith almost in the future of human progress.

If adequate measures are to be taken to deal effectively with the vast subject of preventable disease, it must be by strengthening and not by weakening the public health services. We look, and we believe, not in vain, to the supreme Government to stand four square against this rising tide of ignorance and prejudice.

It is our duty, when the time comes, to hand over the Government of this country to its own population, to see that we leave it with a strong, well organised, and efficient public health service; and that, I believe, is the greatest boon which Western medical science can confer on India.

If the exponents of medical practice in India decide to revert to those "ancient shibboleths of a creed outworn," which we know as the indigenous systems, and to return to the "golden age" of the Rishis, I think it will do less harm than the disastrous state of affairs which will result if the modern principles of hygiene and sanitation are allowed to wither away and to pass into forgetfulness.

The results of research into the causation of tropical diseases are well known to all of you, and if you wish to refresh your memory on this subject, you cannot do better than re-read the presidential address given two years ago at this section by my distinguished predecessor in this chair, Major H. W. Acton, I.M.S. "Research cannot be allowed to end in the laboratory, it is useless unless its principles are brought into actual practice; for only then does it come to full fruition. The difficulty is to bridge this gap which exists between the two."

Research has forged powerful weapons, and has placed them in the hands of sanitarians; but for various reasons, chiefly for lack of funds and from ignorance, want of co-operation or passive resistance on the part of the people, these weapons have not been given a fair chance. It is for an improved and strengthened Public Health Service to use these weapons, to transfer the results of research into the campaign against disease, and so to point the way to the reduction of the vast amount of preventable disease under which India is groaning.

One way in which this may be effected is by closer co-operation between the Medical Research Department and the Public Health Service. The principal laboratories in the country should be provided each with a

mobile laboratory unit whose function should be to proceed at once to the site of any outbreak of disease and ascertain its causation. The nature of the epidemic being known, the official in charge of the unit may consult with the local sanitary authorities as to the best measures for limiting or stamping it out. This principle was acted on with great success during the war in many parts of the world, and it should prove of no less value in peace. Such a unit has been started already in Madras and has already proved its usefulness.

In order to emphasise further the importance of the subject of insect-borne disease, I have arranged a combined discussion by the Sections of Agriculture, Botany and Medical Research, which will be still further strengthened by the presence of experts in Veterinary Science. The subject of discussion is entitled, "Insects and their relation to the diseases of man, animals and plants," and will be, I am sure, a source of interest and profit to all concerned. It will emphasise also the interdependence of these various sciences in the war against tropical disease and the valuable results which may be expected from co-operation of the experts who each in their own department are faced by similar important problems.

In conclusion, if we want a motto for our standards in the war against noxious insects in the tropics, we cannot do better than take the one used by our King-Emperor on a similar occasion: "We speak of preventable disease, but," he added "IF PREVENTABLE, WHY NOT PREVENTED?"

At a combined meeting of the Agricultural, Botanical, Zoological and Medical Research Sections of the Indian Science Congress which took place at Benares on Thursday, the 15th January, 1925, the following proposal was put forward by the President of the Medical Research Section (Lieutenant-Colonel F. P. Mackie, I.M.S.) :—

"In view of the close association between the diseases of man and of domestic animals, the members of the Medical Research Section of the Indian Science Congress would welcome the inclusion in their section of scientific workers in Veterinary Science, which inclusion would be to the mutual advantage of both aspects of pathology. The Section would then be known as 'The Medical and Veterinary Research Section.' This suggestion has the strong support of prominent members of the Indian Civil Veterinary Department."

Mr. J. T. Edwards, Director of the Imperial Civil Veterinary Department, Muktesar, seconded the proposal in the following words :—

"It accorded with the wishes of Veterinary authorities in India, who were sensitive of the compliment paid to them by this welcome to the meetings of their distinguished sister profession at the Congress. They did not desire it to be thought, however, that they wished to desert the Agricultural Section or to dissociate themselves in any way from the agricultural interests of the country by taking this step. In fact, the endeavours of veterinary workers must always be directed to obtain results of economic value to agriculturists, and the problems of animal husbandry were of common interest to both. On the other hand, it was now generally recognised that the problem of disease, whether it be in man, animals, or plants was one and indivisible, and in order to make advances in this field of study it was necessary to have the co-operation of workers engaged in all parts of the field. It therefore seemed that amalgamation with the Medical Section would be more likely to elicit discussion of veterinary contributions from trained workers in the pursuit of research into disease. Veterinary research had the advantage over pure medical research of revealing disease phenomena from the comparative standpoint; manifestations that were obscure in one species sometimes when revealed, in the same or a different species. Again,

investigation could be pursued to greater logical perfection, by the inclusion of the natural host itself in the system of experimentation. Otherwise, veterinary workers stood to gain from the more exalted contributions to knowledge of the medical investigators, who possessed in their ranks much larger numbers of highly trained men and prosecuted their studies ordinarily with greater precision, considerations which seemed to be dependent upon the relative financial (or perhaps, often, sentimental) worth of the subjects of study of the two classes of workers."

Mr. R. S. Finlow, President of the Agricultural Section, added the following remarks:—

Speaking on the resolution Mr. Finlow said that as President of the Agricultural Section he considered that the arrangement arrived at should be that which would best serve the object in view, i.e., the interests of the country at large.

Having in view the series of papers mentioned by veterinary workers to the Agricultural Section this year, it would seem that they might preferably have been read before the Medical Research Section. Therefore although the Agricultural Section would deplore the cry of the veterinary delegates, it could only in the general interest agree to the proposal.

Mr. Finlow added that there would undoubtedly be cases where papers by veterinary delegates would be of such a nature that it would be more suitable to read them before the Agricultural Section. He suggested that this be kept in mind and that due discrimination be exercised by veterinary delegates in apportioning their papers.

The proposal was then put to the combined meeting and carried unanimously. It was resolved to submit the resolution to the Committee of the Indian Science Congress.

At a meeting of the Medical Research Section of the Indian Science Congress on Tuesday, January 13, 1925, the attached proposal was made by the President of the Section (Lieutenant-Colonel F. P. Mackie, I.M.S.) and passed. It was further resolved to send this proposal to the Government of India.

"That the members of the Medical Research Section of the Indian Science Congress now sitting are of opinion that, in view of the vast amount of epidemic and endemic parasitic disease in India, the Government of India and the local Governments should be urged to enlarge and strengthen the Public Health Service throughout the country with a view to reducing the enormous amount of invalidity and death resulting from preventable disease." Proposed by Lieutenant-Colonel F. P. Mackie, I.M.S. The proposal was seconded by Lieutenant-Colonel F. H. G. Hutchinson, C.I.E., I.M.S., A.D.M.S., Allahabad, lately Public Health Commissioner with the Government of India, in the following words:—

"Mr. President, The logical sequence of your interesting and inspiring address is the resolution you have placed before us. You have mentioned the proposals for the reduction of the Public Health Department which arose in connection with the cry for economy. It is not surprising that these proposals were made, for Government action is mainly the reflex of public opinion; not wholly so, for such action should in part aim at creating that opinion. How is it that in the face of some four to six million deaths in a year from preventable diseases in British India, public opinion in favour of prevention of disease practically does not exist. It is obviously the result of a widespread ignorance of what can be done. The importance of this is evident in consideration of the two forces underlying all action for the prevention of disease. The first force is fear or the instinct of self-preservation; this has acted since disease first came into the world, but no permanent advance has resulted therefrom, because its influence is short lived after the calamity which gave it birth. The second force is humanity, the spirit of true humanity which cannot see suffering without the desire to alleviate it. This force has been responsible for the enormous advances in the

prevention of disease made by many countries in the past half century. If this force in relation to disease be dormant in India, it is due to the fact that people do not realise what can be done.

It is by research; by the application of the knowledge gained thereby; by the practical demonstration of the value of such application that this force of humanity will be awakened. The people of India will then cry out in the words of the late King Edward which you have just quoted—"If disease be preventable, why not prevented?" Your resolution, Sir, points the way to the means by which the arrival of that day will be accelerated, and I esteem it a privilege to second it."

The proposal was put to the meeting and carried unanimously.

PUERPERAL SEPSIS. ITS DIFFERENTIATION AND TREATMENT.

A CLINICAL LECTURE TO POST-GRADUATES.

By V. B. GREEN-ARMYTAGE, M.D., M.R.C.P.,

MAJOR, I.M.S.,

Second Professor of Obstetrics and Gynaecology,
Eden Hospital, Calcutta.

GENTLEMEN,—I have asked you to meet me to-day in the Septic Block, because chance has so arranged that I can show you typical examples of those different kinds of puerperal infection which, in one way or another, may become a nightmare to you later on. For in general practice, unless you have a clear conception of the various clinical types of puerperal sepsis, your diagnosis, prognosis, and treatment, will be slipshod, haphazard, and 'shot-gun' like.

Puerperal sepsis is extremely common, and until we can instil *ante-natal* care, cleanliness, and non-meddlesome midwifery, into the old women, nurses, and doctors of this world it will remain so; but please do not run away with the idea that it is necessarily a fatal disease, or that the diagnosis is simple, and the treatment 'rule of thumb.' It is nothing of the sort. Every case is of extreme interest and will test your clinical acumen to the utmost; moreover, please remember in these conditions that your prognosis must not be an immediate one, but that you must think of the remote complications and sequelae.

Before I talk to you of these cases I have collected, perhaps you will let me remind you that, however difficult it may be, prevention is better than cure, and that those scrupulous *ante-natal* and prophylactic measures which every teaching hospital uses in its labour room must be observed in general practice.

Rule No. 14 of our labour room runs as follows:—

"Staff nurses, students, and house staff will please remember that patients with labial affections are not to be examined unless urgently necessary, and that the responsibility of examining such a case must lie with the resident surgeon. This includes such conditions as sores, warts, ulcers, pus discharges, growths, boils, and pustules."

For example let me show you these two cases. One is a lady who was confined outside with forceps, of a baby which died shortly after delivery, and you will see that she has soft sores on the labia, with a sloughing vagina and perineum, complicated by high fever and a discharge in which the gonococcus has been demonstrated.

The other is a full-term patient with an elephantoid condition of the labia majora and ulceration of a granulomatous type of the labia minora.

Speaking gynaecologically, may I remind you that this condition of the vulva we used to think was due to filariasis; now we know that in the majority of cases it is of syphilitic origin. In a lesser number of cases it may be due to tuberculosis or to Leishmania infection. How will you conduct labour in such a case? First let me remind you that the cervix and upper third of the vagina are potentially sterile; therefore let me

adjure you not to examine or apply forceps, for if you do you must carry organisms up into the cervix and uterus. If, however, when the head is low down on the perineum assistance should become absolutely necessary, greatly as I dislike it, I believe pituitrin is the best drug to use, and anyhow is safer than forceps. Indeed, I think it is better to perforate the head with a pair of scissors (*faute de mieux*) than to apply forceps in such a case, for, if the head tears the vagina or lacerates the perineum of these patients, organisms attack the raw surface and the patient frequently succumbs to septicæmia.

Half the battle of the prevention of puerperal fever is the proper management of the first, second, third, and fourth stages of labour.

By this I mean, that during the first stage the bladder and rectum should be kept empty, unnecessary vaginal examinations should not be made, and absolute cleanliness taken as regards hands and skin,—and here perhaps you will allow me to say that every patient in private practice or hospital should be shaved.

As regards the second stage of labour, if you permit it to be too long there is grave danger of the vagina, cervix, and perineum sloughing. Indeed, in this lecture I want to impress on you that half the puerperal patients you will see in Bengal are suffering from one or other of the above conditions.

It may perhaps help you if you will remember a practical rule of mine, i.e.—For an L. O. A., second stage, allow two hours. For a breech presentation, second stage, allow three hours. For R. O. P., four hours; and for a face presentation, 5 hours.

As for the third stage, you must see that the placenta and membranes are intact, and that nothing is left behind.

N.B.—If the perineum is ruptured it must be sutured, but if the case is septic the perineum should never be sutured.

The fourth stage may need an explanation, but it is the term I like to use for the period from the expulsion of the placenta until the tenth day. In this stage it is your duty to promote drainage of the lochia by postural treatment. Quadrupeds rarely suffer from puerperal fever, or lochiametra, because Nature has so arranged that the line of drainage shall be from above downwards and out; but among European patients who lie on their backs for ten days or more, or who sit up in bed to nurse their babies, the heavy, and perhaps flabby uterus, tends to drop backwards, with the result that there is a kink at the internal os, the lochial discharge is retained, and this gives rise to fever.

If you will remember this, and will ask the puerperal mother to lie on her face for 8 hours in every day, you will promote drainage and avoid the anxiety of that low fever due to lochiametra; moreover, if you will adopt this postural treatment which imitates that of the quadrupeds, you will find that your patients will not complain, when they get up and about, of that feeling of "their insides coming out"; for this feeling is merely due to the fact that the heavy, retroverted (and possibly sub-involuted) uterus, lying in the line of the vagina, tends, when the patient stands, to bulge down through the recently stretched and torn pelvic muscle and fascia through which the baby has recently passed out into the world.

The following are the common varieties of puerperal sepsis:—

- (i) Staphylococcic infection.
- (ii) Streptococcic infection.
- (iii) *B. coli* infection.
- (iv) Mixed infection, i.e., either (a) *Streptococcus*, (b) *Staphylococcus* and *B. coli*, or all three together.

Case No. I.—Look at this lady; she is a typical example of a staphylococcus infection, and some of you may remember when she came in that she had had, as you will see from the chart, a temperature of 102° to 104° for the previous two weeks. I informed her relations that she would recover

On what clinical ground was such an assumption based?

1. The history of a long first and second stage of labour, followed by a story of stinking vaginal discharge, pointed to the fact that the cervix and vagina were probably torn and infected with staphylococci which are particularly prone to infect bruised tissues; and those of you who were not here at the time must take my word for it when I tell you that the cervix was torn and of a greenish brown colour, and the discharge very offensive.

2. The slow onset of fever. The temperature, you will see, on the second day was 100°, on the third 101°, on the fourth 102°, after which it ranged between 103° and 104°, and is now subsiding in her fourth week.

3. The pulse was not very rapid.

4. The patient did not look very ill, i.e., she did not wear an anxious expression, nor was there marked anæmia. You will see that now the eyes are bright and the tongue fairly clean after 30 days of fever.

5. The abdomen is not distended nor rigid, though there is slight tenderness on pressure above the pubes.

The Pathological Department found pure *Staphylococcus albus* in her blood, and, despite the fact that her temperature has lasted 34 days, at no time has one felt anxious as to her eventual recovery (although once her relations were far from being so optimistic); but when she completely recovers, by virtue of the treatment we shall speak of later, they will be delighted when I tell them that her chances of future child-bearing are not necessarily jeopardized, for she has been suffering from an infection of the cervico-vaginal cellular tissues and not of the peritoneum, and therefore there is no block or closure of the connection between the ovaries, tubes, and uterus;—a very important point in prognosis which is very often forgotten.

Another interesting fact about this case is that we have been able to isolate the *Staphylococcus* from the urine as well.

Case No. II.—Now come to this bed and look at this girl who is not going to die of a streptococcic infection, despite a nine days exhaustive battle with her disease since she was admitted.

Her history will tell you that within a few hours of labour she had a rigor. This temperature chart will show you the rapid pulse and respirations, and the large oscillations of the temperature during the week she has been here. You will see for yourself the anxious expression, acute anæmia, and sore tongue. The abdomen I will uncover for you and you will see how it is distended, tender, and rigid, because the uterus is infected and the organisms have passed through the wall of the relaxed uterus to the peritoneum, producing peritonitis. The sister-in-charge tells me that she has diarrhoea, but the lochia are not offensive. The Pathological Department report *Streptococcus hamolyticus*.

The picture is complete, and it is certain that some hand or instrument has transmitted organisms through the vagina to the uterus and thence these have passed to the peritoneal cavity and general circulation. Whenever you see a case of puerperal fever with acute anæmia, sore tongue, diarrhoea, and distended abdomen, you may be sure it is a streptococcic infection.

The prognosis in this case fortunately is not hopeless, as, thanks to the modern treatment of which I shall speak later, she will now recover I think.

Case No. III.—Now gentlemen, will you come with me and see this Jewish lady. She is a typical case of *B. coli* infection. You will observe that she gives a history of slight fever before the baby was born (not that that is always so), but please note that the onset of the fever was acute. The temperature chart in a *B. coli* patient is almost typically like our cathedral steeple, that is, it is a spiked chart, up and down, though rigors are not common.

Look at this lady's tongue and feel her pulse. You will see that the one is clean and the other is slow. Her eyes are bright, and there is no anxiety in their expression. There is no marked anæmia and no

diarrhoea. The abdomen is flatulent but not tender nor rigid. There is slight pain when I press hard in the right loin due to pyelitis. The urine, you will see, is of a curious opalescent sheen, and the Pathological Department report "numerous colonies of *B. coli*."

If these cases are more severe than this one, they look exactly like a typhoid case and last for weeks, but they rarely die.

Case No. IV.—Now I want you to come with me into this private room quietly, look at the patient and go out at the opposite door.

This is a patient who was admitted two days ago after being examined and messed about with for days outside. The baby was dead and craniotomy was performed here, but unfortunately she has a mixed infection of *Staphylococcus aureus* and *Streptococci*.

You will observe that she is unconscious, her pulse is 140, and her temperature 105°. The abdomen is distended, rigid, and tender, with peritonitis. She is dying. The case is one of fulminant infection, for, before the blood and lymph sinuses closed, virulent organisms had passed into the general circulation and peritoneal cavity. Long labour and the exhaustion of repeated pregnancies have robbed her of all resistance, and, unfortunately, no treatment will be of avail.

Case No. V.—Finally, let me show you this case in the corner. Here we have a girl aged 16, who had a retained placenta following a long and difficult labour. That placenta was removed manually seven weeks ago, and, contrary to my own teaching, after its removal an intra-uterine douche was given.

If you will look at this case carefully; you will see that she has obviously come through a very long illness. She is thin, anæmic, and extremely weak; and if you will place your hand upon the abdomen you will feel, stretching from the anterior iliac spine to the middle line, a stony hard infiltration; and immediately above Poupart's ligament you will see there is a sinus which leads down into the pelvis for a distance of 4½ inches. The pus from this sinus grew streptococci and *B. coli*. She will recover, but what I want you to realize is, that in removing the retained placenta in a patient who is already septic, there is always the grave danger of organisms which are in the uterus being rubbed in, or grafted into, the raw surfaces.

In this particular case there is a long lateral tear of the cervix leading up to the internal os, which communicates with the cellular tissue of the broad ligament; the leaves of this ligament have been separated by an enormous inflammatory phlegmon, which not only stretches up to the anterior iliac spine, but which also surrounds the rectum, urethra, and the top of the vagina, encasing them as if in plaster of Paris. She will recover, but later she will probably have some stricture or deformity of the urethra, vagina or rectum. These cases of phlegmonous inflammatory exudate are nearly invariably streptococcal in origin.

When I was a student, it was taught, and thought that strictures of the urethra, or vagina, or rectum, were always post-gonococcal in origin, but, seeing how common these conditions are in Bengal, following a history of puerperal fever, I am sure that this is not so, and that such strictures are secondary to streptococcal cellulitis and its subsequent fibrosis.

Only a very small percentage of these inflammatory streptococcal exudates break down and form abscesses.

Now, gentlemen, you have seen these cases. May I then remind you, in view of the different types of puerperal sepsis, of the questions and observations which it is absolutely imperative that you should comply with in any case to which you are called?

1. Enquire as to the history of the labour, whether it was long or not. Whether instruments were used or not; and how long did the first, second, and third stages last?

2. Whether there was any local disease or discharge before the baby was born, remembering the possibility

that the husband may have suffered from venereal disease.

3. Enquire carefully about the placenta and membranes, whether they were intact; also as to the perineum.

4. As regards the fever, make a careful mental note as to whether; (a) the onset was gradual or somewhat deferred, thereby giving you a suggestion that there is retention of lochia; (b) the temperature is high without rigors—suggesting that the fever is due to a staphylococcus infection of a bruised or sloughing cervix and vagina; (c) the onset was acute with rigors—suggesting a streptococcus infection; (d) the temperature is 'steep-like'—suggesting *B. coli* infection.

5. Observe the expression of the face and eyes, noting carefully whether there is anæmia, or no, and whether the tongue is clean, typhoidal, or sore.

If there is acute anæmia, and the tongue is red and sore, and the pulse very rapid, these cases are always due to streptococci and are of the worst prognosis. On the other hand if the tongue is clean, the eyes bright, and the expression not anxious, then it is as a rule a case of *B. coli* infection.

If the tongue is typhoidal it is probably staphylococcal or a mixed infection.

6. Never forget to expose the abdomen and observe whether there is pain, rigidity, or distention. Generalized pain and rigidity, especially if it be accompanied by distention above the umbilicus, is nearly always of streptococcal origin. If the tenderness and distention be below the umbilicus, and the uterus be palpable, the probabilities are that the infection is with the *Staphylococcus* or *B. coli*.

7. Next enquire carefully as to the discharge, whether there is any smell. If so it is nearly certain that it is due to staphylococci or *B. coli*. If there is no smell, the probabilities are that it is a streptococcus infection.

8. Enquire about a catheter specimen of the urine. Whether it is clear and acid—suggestive of *B. coli*. Whether it is concentrated or highly coloured, suggesting *Staphylococcus*. Whether it is smoky, indicating acute nephritis secondary to streptococci.

TREATMENT.

1. The commonest cause of all fevers after childbirth is, I think, *lochia metra*, due to a clot, or membrane, or kink (caused by a falling backwards of the uterus), damming back the natural discharge.

The treatment of this condition, as I have already pointed out when speaking of the patients I have shown you, is:—(a) *Postural*, i.e., making the patient lie upon her face, or in Sim's position, for eight hours out of the 24. (b) Hot vaginal douches four-hourly. (c) Hot rectal saline douches b.d. (d) Ergot and pituitrin. In most cases this is all that is necessary. If the low fever does not subside, or recurs, then merely putting a gauze or tube drain into the uterus is sufficient.

2. The next most common cause of high fever is undoubtedly a *Staphylococcus* infection, caused by a sloughing of the cervix, vagina, or perineum after a long labour. The treatment of these cases is:—(a) Prop the patient up in Fowler's position and give four-hourly vaginal douches, and hot rectal saline douches b.d. (b) A mixture containing potassium citrate and bicarbonate of soda; for many of these patients have a nasty habit, if the fever continues long, of complaining about the seventeenth or eighteenth day of severe pain in the leg or thigh, and the next morning you find they have phlegmasia alba dolens (white leg). I think the above given in big doses, or citric acid gr. 20, t.d.s., lessens the chances of such occurrences. I, myself, am a great believer in hot rectal douches for these cases.

N.B.—Never give an intra-uterine douche, for the nozzle passing through the septic vagina and cervix carries organisms into the uterus which may directly infect its walls.

Indiscriminate intra-uterine douching is, in my opinion, a most disastrous procedure, for I have records of

over fifty cases where rigors or generalized infection occurred subsequent to this operation; for, as I have previously demonstrated to you, the pressure at the Budjín or Bozeman nozzle from the raised douche can be equal to seven pounds to the square inch. Hence you can easily gather how this pressure tends to push the germs into the lymph or blood sinuses when there is a raw, or jagged endometrium present in the relaxed uterus; to say nothing of the fact that in miscarriage cases the uterine ends of the Fallopian tubes are patent till the sixth month, and so the douche pressure may carry organisms directly to the peritoneal cavity.

3. Next in order of frequency are those cases where there is a history of *bits of membrane and placenta left behind*.

Our researches here prove that in these the puerperal sepsis is nearly always staphylococcal, and my own opinion is that Professor Watson of Edinburgh sounds the correct alarm when he advocates almost complete non-interference.

My own practice is as follows:—

If I know that a large piece of membrane, or I suspect a portion of the placenta, the size of a dry walnut, to be still retained and adherent (as in a recent case you saw), I cover the ends of a pair of sponge-holding forceps with sterile gauze and use this for investigation purposes. I find that these forceps thus dressed make a most adequate remover of bits, for no mere man's finger covered with gauze can explore or reach to the top of a recently parturient uterus. If, on the other hand, I suspect only shreds or small portions of membrane and placenta to be retained I do *not* explore but treat her in exactly the same way as I have told you for lochiametra.

The principles of your treatment should be:—

(1) *Never* give an intra-uterine douche, for the reasons I have given you above.

(2) *Never* curette, however blunt your instrument.

Order:—(a) hot vaginal douches every four hours, and hot rectal douches twice daily; (b) ergot and pituitrin; (c) sit the patient up in Fowler's position, and let her lie in Sim's left lateral position, or on her face, for eight hours daily.

If you suspect from the celerity of the pulse that there is a blood infection, a blood culture should be made.

4. As regards *streptococcal infections*.

These are the gravest of all, but what I want you to realize to-day is, that, thanks to the Gordon Luker technique in private and in hospital practice, we are now able to reduce the mortality. The last five cases of *streptococcal infection* I have seen in consultation have been extremely severe ones, and happily, despite the usual pessimism on the part of the practitioners, have all recovered; and in three of the cases streptococci were found in the blood.

Dr. Gordon Luker advises: (a) 30 c.c. of anti-streptococcal serum hypodermically for three consecutive days at whatever stage of the disease you may see the patient. At the same time five grains of quinine hydrochloride are given intramuscularly into the buttock every other day for six to ten days. In very severe cases he gives the quinine intravenously.

As regards this technique, there is just one more point, and that is, that the quinine solution must be massaged into the tissues immediately after injection in order to prevent local necrosis. (b) Sit the patient up in Fowler's position and give rectal saline. (c) If an autogenous vaccine can be prepared, so much the better.

When working on this subject here between 1910 and 1914 I found, post mortem, that in a large number of these cases there was a big collection of thin ichorous fluid in the pouch of Douglas. I still think, now, as then, that where you suspect such fluid on vaginal examination, it should be evacuated by a posterior colpotomy (Pryor's operation).

These cases of *Streptococcus* infection need most careful nursing, and large quantities of stimulant are necessary, for frequently the patient dies of cardiac toxæmia. Since the War I have been giving in very severe cases intravenous injections of tincture of iodine, 10 to 15 m. doses in a like quantity of sterile water every day. I am afraid I cannot tell you how it acts, but I am perfectly certain it is of great benefit in many cases. My impression is that the iodine stimulates the thyroid gland, for I have noted that this gland has become more swollen subsequent to the injections. As you know, I look upon the thyroid gland as the sparking plug, or detoxicator of the system. Perhaps the iodine whips the gland into action out of the coma caused by the infection. Recently I have been reading Vine's book on the parathyroids and I am inclined to think that, where the above methods have failed, parathyroid extract given in one-tenth grain doses may be another weapon of offence against streptococci, for it raises the leucocyte count.

5. *B. coli* infections are not uncommon, and as a rule do not give rise to any great anxiety beyond the fact of the fever, for the patient herself hardly seems to realize that she is ill. Her tongue, her face, her eyes, her pulse, her belly, all should give you the clue. The finding of leucocytes in a limpid acid urine may help you where a bacteriologist is not at hand. All that you do in these cases is to saturate the patient for 3 to 5 days with three-hourly doses of the following mixture:—

Sodium Bicarbonate	..	1 dr.
Potassium Citrate	..	1 dr.
Water	..	1 oz.

In nine cases out of ten the fever will subside, but beware of relapses.

My experience is, that if you keep a patient on this prescription for a week, and then for another week on

Urotropin	..	10 grs.
Ammonium Benzoate	..	15 grs.
Acid Sodium Phosphate	..	20 grs.
Water	..	1 oz.

t.d.s.

your anxieties will cease. At the same time the patient is given vaginal douches four times a day, and rectal douches b.d.

Where I have thought the infection was mixed with staphylococci I have given tincture of iodine intravenously as before.

If an autogenous vaccine is procurable, give it in progressive doses commencing with fifty million.

PROGNOSIS.

1. Hitherto pure *Streptococcus* infection has caused an eighty per cent. mortality in this hospital. I hope now, both in Calcutta and in the mofussil, that this mortality will be greatly reduced by the methods I have indicated, for Dr. Gordon Luker has reduced the mortality at the London Hospital to approximately thirty per cent.

2. *Staphylococcus* and *B. coli* infections. These rarely cause the death of a patient, but, consequent to the debility and secondary anæmia of sepsis, many of these patients develop some inter-current disease, such as pneumonia. Others develop multiple arthritis, and some of you may remember a typical case which I showed you recently of a girl who had an ankylosed elbow joint, and a flail-like hip joint with such grating that you could hear this at five yards distance when I moved the head of the femur against the osteophytes around the acetabulum. The history was that she had had three months fever following the birth of a dead baby. She is pregnant again with a markedly contracted pelvis and cicatricized vagina and cervix. I am going to do a Cæsarean section. Other patients develop localized abscesses which run a very distressingly long course. There is a patient in the European Surgical Ward who

has had up to date eleven deep muscular staphylococcal abscesses opened subsequent to a long labour.

Please do not forget that if the patient develops inflammation of the peritoneum, which involves the tubes and ovaries, she is likely to become a chronic invalid and suffer from sterility. Indeed, perhaps the commonest cause of one child sterility in Bengal is just such a condition; whereas if all the symptoms and signs point to an extra-peritoneal phlegmonous exudate (i.e., an infection of the broad ligament or tissues around the vagina), that patient, when she gets well, is capable of conceiving again because the tubes and ovaries were not necessarily involved in the original inflammation. This, you will clearly realize, is the reason why, despite a long history of puerperal fever (such as in the case of the girl I have just mentioned), one frequently hears that a patient is pregnant again.

Unless, therefore, either clinically, or from the history you are absolutely certain that the pelvic peritoneum is, or was, involved, do not give either an immediate or remote bad prognosis.

3. *B. coli* infections, as I have told you, are very liable to relapses and this, coupled with the fact that the fever goes on for a very long time, frequently cause them to resemble typhoid fever.

Please therefore remember that unless your treatment is adequate your patient may suffer from chronic inflammation of the kidneys, bladder, or possibly gall-bladder.

It is of importance to remember that on microscopic examination of a catheter specimen of the urine in cases of puerperal sepsis, one may occasionally obtain a pure growth of staphylococci, which is the cause, or clue to the cause, of the prolonged fever.

Current Topics.

The Wasting Infant.

By ROBERT HUTCHISON, M.D., F.R.C.P.

(British Med. J., May 17, 1924, p. 847.)

WASTING may have different causes.

Organic Disease.—Tuberculosis is not common during the first six months of infancy, when wasting usually occurs. Nor it is likely to occur without producing some evidence of its presence in the shape of physical signs in the chest, abdomen, or glands, although occasionally it is found after death when its presence had not been suspected during life. A syphilitic "taint" may interfere with nutrition, and it is possible that some of the wasting infants who improve so remarkably under the administration of grey powder, as some of them undoubtedly do, may be affected in this way. If in doubt, a blood test should settle the matter.

Diseases of the lungs, such as chronic broncho-pneumonia and "latent" empyema, may be unsuspected causes. Wasting may be due to insufficient intake of food. A common cause is the use of condensed milk in too high a degree of dilution or the giving of small feeds.

Premature infants are very apt to waste. Too large or too strong feeds may cause wasting. Oftener the error consists in giving an ill-balanced mixture which is too rich in one of the food constituents, a relative excess of fat being the commonest fault.

Dyspepsia is so common, either as a cause or as a concomitant of wasting, that there are few marasmic infants who are not also dyspeptic.

The symptoms of dyspepsia may arise suddenly, as in cases of summer diarrhoea, but more frequently the dyspepsia comes on gradually as the result of the continued use of an unsuitable or ill-balanced diet.

Excess of fat in the diet is indicated by constipated, pale, crumbly or soapy stools. Excess of casein is much less likely to be a source of difficulty, and when it occurs leads to vomiting of curd and the passage of tough white particles in the stools. Sugar is the least likely to lead to trouble, but if present in an amount which is beyond the infant's digestive capacity the stools are apt to be loose, watery, and acid, and their passage attended by much flatulence. Usually the digestion of all the food constituents is impaired. The true nature of such cases has so far baffled us.

It is to primary or idiopathic wasting of unknown cause that the term "atrophy" should be specially reserved. There does not seem to be anything wrong with the food and there are no signs of dyspepsia, but the child simply wastes, and after death no cause can be found for the failure of nutrition.

Wasting is apt to become attended by complications. Such babies are very prone to infections by pyogenic organisms which cause boils and abscesses, by the tubercle bacillus, and by the *B. coli*. They are also very apt to contract an infective enteritis or a broncho-pneumonia.

The prognosis in a case of wasting is always doubtful. There is always the possibility of an abrupt collapse which proves fatal, or a sudden and seemingly spontaneously improvement may occur at any moment even in the worst cases. The worst cases are those in which everything seems to be right except the power of gaining weight.

The treatment is not merely dietetic—the general hygiene of the infant is of the first importance. Over-feeding is more perilous than under-feeding, and one must not be too ambitious in the matter of increasing the weight.

Always change the feeding reluctantly, cautiously, and never without good reason, bearing in mind that fat is the ingredient most likely to cause trouble. Before starting a new food it is well to clear out the bowels with a small dose of castor oil, and if acute symptoms of "intoxication" have supervened to suspend all food (except glucose and water) for a few hours, but not for long, remembering that wasted infants stand starvation badly.

Breast milk is the best food in most cases, but is unfortunately often unobtainable. In selecting an artificial food, begin with one which is rather poor in fat and relatively rich in carbohydrate and whose protein is in a digestible form. Sweetened condensed milk (2 drachms to 3 ounces) or a half-cream dried milk (1 drachm to 1 ounce) with the addition of dextri-maltose fulfils these conditions. It may be necessary to feed on a mixture of whey and Mellin's food (dextri-maltose) or whey with the addition of a modified starchy food; if casein is the difficulty the milk should be fully peptonized or citrated; or a dried milk may meet the case.

The more wasted and exhausted the child is, the smaller and more frequent must the feeds be. Drugs are of little use. Grey powder sometimes does good, even in cases in which there is no reason to suspect a syphilitic taint. Alcohol is also helpful, especially if there is much exhaustion.

"You will lose a good many of your marasmic babies in spite of all your care and skill, the fault in many cases is in the child and not in the food, and once the disorder has progressed to a certain length no treatment makes any dramatic difference."

Medical Education.

EXTRACTS from an editorial in the *Journal of the American Medical Association* of October 11th, 1924:—

"In a recent address delivered by Dean Edsall of the Medical School of Harvard University before the Massachusetts Medical Society, he asserts that the standards existing in the United States of America represent not an extreme reached in a period of exaltation, but a tardy arrival at approximately the same standards that had

already been reached by most other highly civilized countries, in nearly all of which financial conditions are much more difficult than here. It is not insufficient numbers but rather unsatisfactory distribution that represents the problem to be solved—a condition that is not peculiar to the United States. Dr. Edsall warns that reducing medical standards would not cure the faulty distribution of physicians, unless those who are briefly and badly trained went especially to the country regions, and there is no evidence that they have done this extensively, or would do it. On the other hand, it is obvious that this would be a highly unintelligent way of meeting the need for physicians in the country regions, and would be clearly recognized as such by intelligent people who employ them; probably it would be resented.

Is medical education justly open to the charge that it has become too scientific? If this refers to the seemingly endless accumulation of more or less isolated facts and to the multiplication of experiences in technique, the fear may be warranted. Edsall would assert that such recent graduates who have 'a conglomerate of information and of technique relating to the sciences which they cannot use very effectually to illuminate their work, the rationale of which in relation to their life effort they do not really comprehend,' are not trained too scientifically but too unscientifically. They have missed the essence of the search for truth and the powers that develop it."

This view of the subject of medical education should be given due attention in India where exactly similar problems have to be faced.

A Daily Medical Newspaper.

THE city of Barcelona has always been noted for its enterprise, and it has now added to its other claims to greatness the inception of a daily medical newspaper, *El Dia Médico*. The first number runs to eight pages of printed matter, and there is a portrait of Dr. Ramon y Cajal, the distinguished histologist, on the front page. The editorial by Dr. Paul Weckesser is on bismuth therapy in syphilis, and full of information. Notes on interesting cases are given, and notices of medical meetings for the day. We wish our enterprising contemporary success, and a long career.

An Investigation into the Causes of Dysentery Prevalent in some districts of Eastern Bengal.

(Abstract of a paper read by Capt. P. Ganguli, B.A., N.M. (Bengal), at the Medical Research Section, Indian Science Congress, January 1925.)

Out of 62 cases of severe dysentery admitted for treatment to the Dacca Mitford Hospital, the following causative factors were seen.

E. histolytica (vegetative) was seen in 19 cases (30 per cent.); *E. histolytica* cysts were detected in 7 cases (11 per cent.); Charcot Leyden crystals were found in 8 cases (12 per cent.). The total percentage of *E. histolytica* infection was 53, if the presence of Charcot Leyden crystals be accepted as proof of *E. histolytica* infection.

Shiga bacilli were responsible for 18 cases of dysentery and Flexner group bacilli for 4 cases, giving a total of 22 cases out of 62, the percentage being about 35.

Out of these 56 cases, 7 showed mixed infection of both *E. histolytica* (cysts present) and Shiga bacilli, the reaction of the stools being alkaline (pH 7.5 to 8.5) in all the seven cases. Three dysentery cases showed *Trichomonas* and one of them *Lambia* cysts as well.

In three cases no definite causative organism could be ascertained. In two, however, numerous fungi were seen. *Endomyces tropicalis* and yeast cells were most abundant and there were also *Aspergillus* and *Mucor* in large numbers. Starch and sugar were withheld from their dietary. The patients were put on albumen

water and improved considerably. Both these cases relapsed on sugar being added to their diet. The patients made an uninterrupted recovery after being put on albumen water and gelatine solution for 7 days. The reaction of the stools was highly acid (pH 6.5 and 6.3 respectively).

Incidence of Flagellate and Helminthic Intestinal Affections in Eastern Bengal.

(Abstract of a paper read by Capt. P. Ganguli, B.A., N.M. (Bengal), at the Medical Research Section, Indian Science Congress, January 1925.)

THE medical wards of the Mitford Hospital, Dacca, admit patients from Sylhet, Comilla and Mymensingh districts in practically equal proportions. The total number of patients coming from these districts is nearly equal to the number of patients coming from the Dacca district proper. It will thus be seen that the figures obtained from the examination of stools of the indoor patients of the medical wards of the Mitford Hospital is a fair index of the incidence of flagellate and helminthic intestinal affections in Eastern Bengal.

Out of 256 samples of stools examined from January to November, 1924, 91 belonged to kala-azar cases, 60 to dysentery cases, and the rest to miscellaneous diseases. The result of examination of stools was as follows:—

I. Human Intestinal Flagellates.

<i>Trichomonas hominis</i>	.. 43 or 17.	per cent.
<i>Chilomastix</i> (Tetramitus)		
<i>mesnili</i>	.. 41 or 4.56	per cent
<i>Giardia</i> (<i>Lambia</i>) <i>intestinalis</i>	.. 11 or 4.3	per cent
<i>Enteromonas</i> (<i>Cercomonas</i>)		
<i>hominis</i>	.. 7 or 2.7	per cent.

II. Helminthic Affections.

Nematodes:—

<i>Ankylostoma duodenale</i>	.. 68 or 27.47	per cent.
<i>Ascaris lumbricoides</i>	.. 33 or 12.89	per cent.
<i>Trichocephalus dispar</i>	.. 15 or 5.85	per cent.
<i>Oxyuris vermicularis</i>	.. 8 or 3.125	per cent.
<i>Strongyloides stercoralis</i>	.. 4 or 1.6	per cent.

Trematodes and cestodes:—

None were observed in the stools of the indoor patients.

It will be seen from these figures that the incidence of *Trichomonas* (17 per cent.) is rather high in comparison with Major Knowles' Calcutta figure of 1922. He found it present in 18 out of 233 stools, giving a percentage of 7.7. Wenyon's percentage was 3 in 550 persons examined.

The incidence of *Chilomastix* is very low in Eastern Bengal. Knowles' Calcutta figure for 1922 gave it as present in 22 out of stools of 185 patients, showing a percentage of 8.4, in comparison with 1.56 in Eastern Bengal.

Giardia infestation in Eastern Bengal (4.3 per cent.) approaches closely to Wenyon's figures, viz., 5 per cent. The Calcutta figure gave it as present in 8.8 per cent.

Observations on Malaria Control, with special reference to the Assam Tea Gardens, and some remarks on Mian Mir, Lahore Cantonment.

By SIR MALCOLM WATSON, M.D., C.M., D.P.H., LL.D.
(From the Transactions of the Royal Society of Tropical Medicine and Hygiene,
23rd October, 1924.)

"EARLY this year I visited a large group of tea estates in Upper Assam for the purpose of advising on the control of malaria, which was prevalent in the gardens. During my stay of three months I had also an opportunity, through the courtesy of the medical officers, of seeing a number of other gardens and enquiring into their health conditions. From what I saw myself, and also from what Professor C. Strickland told me, malaria

is spread widely throughout Assam. As a result of malaria and other diseases and the generally insanitary conditions which formerly prevailed, the death rate of the labour forces was high. But, thanks to the admirable work done on the various gardens, the very high death rates were things of the past. I was much struck by the excellence of the work done on the gardens, and I think the medical officers of the tea gardens in Assam have reason to be proud of the record of their work. To-night I propose to discuss briefly, illustrating my remarks by lantern slides, the general nature of the work which has lowered the death rates of the gardens, and then to discuss the light this throws on the present feeling towards malaria control in India generally, and of malaria in Mian Mir, now called Lahore Cantonment, in particular.

Before considering the conditions seen in Assam, I should like to show you a few slides illustrating the methods of malaria control in the Federated Malay States.

1. First come the tide gates and deep drainage of the mangrove swamps, illustrated by Port Swettenham and Carey Island. On the island, over 20 sq. miles have been cleared of jungle, and drained, with practically the complete abolition of malaria. The spleen-rate of over 900 children is 0.9 per cent. The carriers of malaria were *Anopheles umbrosus* and *A. ludlowi*.

2. Then comes the open drainage system of the coastal plains. Malaria was carried by *A. umbrosus*. It and the malaria disappeared with the drainage and cultivation of the land.

3. In the coastal hills there was malaria from the presence of *A. umbrosus* when the ravines were covered by jungle, and from *A. maculatus* when the ravines were cleared. We escaped from the dilemma by putting the springs and streams in subsoil pipes, and using refuse oil. In Singapore the Health Officers have saved some 35,000 lives since they began the work in 1912. In Kuala Lumpur it was the best residences in the town, those belonging to the highest government officials, which were most severely attacked. Quinine and general sanitation failed. Salvation came by a direct attack on the mosquito.

4. To Dr. Strickland we owe the observation that the inland hills are free from malaria when they are under jungle, because *A. umbrosus* does not breed in them. They become malarial only when cleared, for then *A. maculatus* appears.

5. Our inland plains are not large in extent; they are, however, more or less malarial, depending on the extent to which *A. maculatus* and *A. minimus* (syn. *albipennis*, *aconitus*, *listoni*) find the local conditions favourable.

6. On the coastal plains, rice-fields are generally healthy, while in the valleys they are generally unhealthy. On the plains the *Anopheles* are *A. rossi*, *sinensis*, *barbirostris*, *kochi*; while in the valleys, *A. minimus* and *maculatus* are added. In the last twenty-four years a good deal of work has been done in Malaya, and the results may be summarised pretty fairly as above.

Now Malaya is a land covered by an evergreen jungle, in a moist climate, with a high rainfall, and temperature which ranges roughly between 70°F. and 90°F. every day of the year. Some months are much wetter than others; but long periods of dry weather are unknown. If we have three weeks of dry weather we are all grumbling. From the combination of temperature and rainfall, you will readily understand that Malaya has a rich anopheline fauna; a fauna which reaches up into Assam, for the countries have a direct land connection through Burma, and, as Colonel Christophers has pointed out, the conditions in Assam and Eastern Bengal approximate, perhaps, more closely to those of Malaya in the past than they do to-day in rainfall and, therefore, in jungle, etc.

The Assam Valley, in the upper or eastern part of which I spent my time, is bounded on the north by the Himalayas, and on the south by a mass of hills, which cuts off India from Burma. At the eastern end of the

valley the hills are known as the Naga Hills. I understand that great faulting has occurred on the south side of the valley, but, generally speaking, the valley represents a deep trough between the two masses of hills to north and south. The trough has become filled by detritus from the hills. There is evidence that at one time it formed an estuary of the sea. However that may be, the present land surface of the valley is a fine alluvial soil, the great asset of the tea gardens.

The Brahmapootra ploughs its way down the valley, rather on the northern side, while many other rivers are cutting their way through it, in a manner which I shall shortly explain.

In the slides you will see a broad flood plain, bounded by high banks and traversed by a winding, living river. You will see two dead loops of the river, where it has changed its course. In other photos you will see this loop gradually becoming silted up, until it reaches the general level of the flood plain.

Originally the flood plains were under jungle; with the opening up of the estates, the coolies have cleared away the jungle to plant rice. The river plains were too wet for planting in some places, e.g., along the edge of the high bank or "khud," especially where the river was at the opposite side of the plain; and in the dead rivers before they had been filled up.

In these places I found *A. maculatus* and *A. minimus* in abundance, and I was not surprised to find much malaria.

On land such as I describe, I examined various groups of children, totalling 9,146. Their spleen-rate was 69 per cent. Of these, 2,416 of two years and under, 61 per cent. had enlarged spleens, so we were evidently dealing with intense malaria.

Cattle, which were in great abundance, seemed to give the coolies little protection.

The percentage of the various species of *Anopheles* caught differed in cowsheds and houses. The following are the figures for *Anopheles* caught between 25th January, 1924, and 23rd February, 1924:—

	<i>A. fuliginosus</i> .	<i>A. minimus</i> .	<i>A. sinensis</i> .	<i>A. maculatus</i> .	<i>A. gigas</i> .	<i>A. rossi</i> , var. indef.	<i>A. barbirostris</i> .	
Cowsheds	2054	42	28	10	0	0	1	2135
Houses..	60	95	45	7	2	1	0	210

The finding of *A. gigas* at a level of under 400 feet above sea-level is new. Larvæ were also found. They could not have been washed down from the hills.

The estates which I was advising are universally regarded as amongst the very finest in Assam. They are wealthy, well managed, and have spared no pains to make their labour forces healthy, happy and contented.

The slides show how well the coolies are housed. The old groups of coolie lines are being steadily broken up, and the people given individual houses, each with its garden. Some of the gardens have good piped water supplies; others brick wells. Some have latrines of a good type; others buckets. A few have none.

The pregnant women are given full pay or food for some months before and after their confinement, and are not allowed to work. The children are given one full meal free of charge each day. Any adult who is not fit for a full day's work, or who has recently been discharged from hospital, is put into a "Challan." He does only such work as the medical officer prescribes, and is given pay and food.

Practically everything anybody could think of to strengthen the coolies in their fight against disease is being done, and the result has been a notable diminution in the death rate. But the fact remains that all these

measures fail to prevent the coolies becoming infected with the malaria parasite. It helps them to acquire immunity: and I gathered the impression that, to a certain degree, immunity was inherited by the children. Nevertheless, 69 per cent. of the children on the gardens had enlarged spleens.

In Assam, as in the Malay States, no amount of quinine and general sanitation or education of the people is of any avail to stamp out the disease. Nothing but a direct attack on the mosquito can give the desired result; and that I recommended.

There were two ways of controlling the insects. One was to remove all coolie lines to a central spot, and to abolish all breeding-places within half a mile. This would have been very expensive, for it would have cost a large sum to remove and rebuild the coolie houses, and an even larger sum in loss of profit from cutting out 100 acres of tea in each 1,000 acres.

The other method was to leave the coolies where they are, on the edge of their rice-fields, and to strike at the two dangerous *Anopheles*, namely, *A. maculatus* and *A. minimus*. Before deciding on this, I examined a number of estates to ascertain if healthy rice-fields existed in Assam, as they did in the Malay Peninsula, Java, British Guiana, and other parts of India, and generally what the nature of malarial land was in Assam.

I show you some photos which illustrate what I found.

The physical features associated with malaria were:—

1. River valleys, whether large or small, but not when as large as the Brahmapootra at Dibrugarh.
2. Swamps and "bils" in dead river beds, or in the flood plains of living rivers.
3. Natural hollows or water channels, which may be dry in the dry season.
4. Narrow rice-fields under certain conditions, especially in land above the 400 feet level.
5. Wet waste land, "Kurkani land" and some thatch land.

The physical features not associated with malaria were:—

1. Broad, flat rice-fields.
2. Old broad, dead river channels, dry in the dry season.
3. Dry thatch land, if not "Kurkani."
4. Bamboo clumps.
5. Some brickfields.

Generally speaking, the lower and flatter the land the lower the spleen-rate. As in the Federated Malay States, the higher the land, the better the opportunity for *A. maculatus* breeding, the higher the spleen-rate.

In Assam it was among the best and the best managed estates that malaria was most prevalent; not because of neglect of sanitation or any other general measure, but because of the nature of the land and the presence of certain species of *Anopheles*.

In Kuala Lumpur, in the Federated Malay States, malaria was worse among the best housed and best educated people.

In Havana, as General Gorgas tells us, small-pox had been entirely eradicated. But the great result at which we aimed seemed to be as far away as ever. "Our sanitary measures, if they had any effect on yellow fever, seemed to increase it. The cleanest and best built part of the city seemed to suffer most from the disease, and the best fed and best cared for part of the population was that which had the largest rate of deaths from yellow fever. It was the well-to-do class of Americans and the highest officials on the staff of the Governor-General who suffered out of all proportion to the rest of the population. It looked very much as if the cleaner and better hygienically we got the city, the worse we were making yellow fever."

This does not mean that education and general sanitation are valueless; but I can find no evidence that they can control either malaria or yellow fever. Accordingly, a system of drainage to strike at *A. maculatus* and *A. minimus* is now under construction, some photos of which I show you. Oil will be applied where neces-

sary. Cinchona is being given to the children and fever cases.

With all these measures together I have little doubt that we will soon have the disease under control.

MIAN MIR.

From Assam I went to the Punjab and visited Mian Mir, or, as it is now called, Lahore Cantonment. I speak of it not with the idea of reviving an old controversy in any bitter spirit, but for the sake of discussing whether or not the methods adopted between 1902 and 1908 for the eradication of malaria were the ones we should use to-day, were the work to be done; and if the conclusions drawn by the Commission of 1910 are the last words to be said on the subject. For if they are, then I think the prospects of freeing the Punjab, and many other parts of India, from malaria are slight indeed. It is to me like passing a death sentence on millions of people. I believe there is a brighter outlook.

In Mian Mir, in the past, I think there is little doubt that serious mistakes were made. But then it is true that he who never made a mistake never did much. It must not be forgotten too that this was the first attempt to control malaria in India, and that the presence of the irrigation system complicated the problem and confused the issue. Let me candidly admit that for some years we cleaned up the ravines in our hill land, making malaria the worse. We had to adopt an entirely different method. Let me remind you too that in 1901 when the Federated Malay States Government gave me the money to clean up Klang, Dr. Braddon applied for money to clean up Seremban—a town on the main range. Presumably he would have felled jungle and "trained" streams, and would have caused a big outburst of malaria in, at that time, a healthy town. Had that occurred I can imagine the progress of malaria prevention in the Federated Malay States would have been seriously retarded, as it has been in India by the experiment done in Mian Mir.

Now I do not propose to discuss the statistics of Mian Mir, or what was done by the various people in charge between 1902 and 1909. The broad fact remains that they did not achieve the results expected; and even to-day Mian Mir has an evil reputation as a malarial cantonment.

The Commission appointed in 1910 concluded, from their inspection of Mian Mir, that the problem of malaria control in India was one of great complexity, and that large and costly schemes, such as had been carried out in other countries, were beyond the resources available in India.

They thought that the work of the immediate future lay in patient and searching investigation and in careful and continued experiment. With that I entirely agree, but the war stopped all chance of investigation and experiment. The Commission also concluded that the active co-operation of the people and the general amelioration of the insanitary conditions of life which are potent factors in augmenting the disease, are essential if malaria control is to be successful. "Such amelioration must come in the main from the people themselves, and their education thus lies at the root of the problem." With this I disagree.

I have told you what I have found in Malaya and Assam; I am, therefore, in total disagreement with the final conclusion just quoted. No amount of general sanitation, nor universities crammed with receptive students dotted all over the Punjab, will clear malaria from India unless the mosquitoes which carry the disease are destroyed, or some medicine, vastly more effective than quinine, is discovered.

Looking at Mian Mir with the experience of twenty-four years' work on malaria to guide me, I came to the conclusion that:—

(a) The cantonment is not and never has been properly drained. This is practically admitted in the 1910 report.

(b) The Royal Artillery bazaar, where the experiments of 1902 and 1903 were carried out, is furthest

from the drainage outlet, and the 1910 report says this area could not be effectively drained (p. 16, par. 42).

(c) Assuming that there is no available outlet for the drainage, the question of pumping out the water with a centrifugal pump does not seem to have been considered, yet, as I have shown you, it is effective and economical on an estate in the Federated Malay States, in spite of a rainfall of four or five times that of Mian Mir.

It seems to me that the whole question of the control of malaria in this cantonment should be reconsidered, in the light of what we know of malaria control to-day, and I believe that, were an experiment conducted on such lines carried to a conclusion, the present rather pessimistic view of the future of malaria control in India would disappear as the dim old miasma hypothesis faded before the light and warmth of the illuminating genius of Ronald Ross.

In conclusion, I should like to pay a tribute to the wonderful contributions made to medical science and public health by the Indian Medical Service. This Service has earned a deserved reputation throughout the world, and I am sure it will realise the importance of dealing with the urgent problem of malaria control in Mian Mir and other parts of India, and in resuming the work commenced and abandoned so many years ago."

DISCUSSION.

Sir Ronald Ross: I have not got much to say. I am very glad you began, Sir, by congratulating Sir Malcolm Watson on the honour which has been conferred on him by the King. It is highly deserved, after nearly a quarter of a century hammering away at this one piece of work. Also we must congratulate him on the honour he has received from the University of Glasgow. He is going back to-morrow, full-fed with honours, and with some dinners, etc.

This work of his has really been very great. I do not think we in this country quite understand it. We know the work done in America by Gorgas, and that was splendid work—I am not likely to depreciate that—but we must remember that, both in Havana and in Panama, Gorgas had behind him the full wealth of the United States Government, and that was a great advantage, too, in the Panama Isthmus Commission. The reduction of malaria in those places was a state affair. The matter was quite different with Sir Malcolm Watson. He started his work—this antimalaria work—at about the same time as Gorgas, a quarter of a century ago, and he worked at first almost by himself. There are some names associated with him: Hamilton Wright and Travers helped him, and there was Professor Strickland, and now, recently, Dr. Scharff, who has been working in Singapore. But Sir Malcolm had to raise the money and do the work at the same time, and everybody knows that is not an easy job. He had to persuade the planters to use his methods, and he had to talk, and very persuasively, to hundreds of people. It is one thing to kill the mosquitoes, but it is a much more difficult thing to get money out of the pockets of the planters, and that is what he had to do. He has continued that work for a quarter of century, with results that he has not given sufficiently in this lecture. He could have gone on for another two hours telling us more details of the work. I think what he has done has added immensely to our knowledge generally. It shows how different species of mosquito must be dealt with in different ways. But it all comes to the same thing in the end: it brings us to the rule—which I was, perhaps, one of the first to lay down, about a quarter of a century ago—that there should be no stagnant water round settlements. He has shown that you must deal with each species of carrying mosquito on its own merits or basis.

I agree with his last words about Mian Mir. I will not say anything about the old fights we had about Mian Mir, but I strongly advised the Indian Government to take up the subject, and not have to own to the

defeat of mankind by the mosquito. The mosquito kills in this world, I think, something like two million people a year, and that is a low estimate; it is a greater mortality than was caused by the war. The mosquito is a terrible enemy of mankind, and we must set ourselves to oust it as much as we can from the centres of population. I refuse to admit I have ever said you can get rid of mosquitoes all over the world, but perhaps if we had spent as much money in reducing mosquitoes as we have in killing each other in the recent war we might have achieved it. But I think we should smarten up this war, and that all planters should try to get rid of malaria from their own plantations.

I will deal with only one more point. Removing mosquitoes costs money, but the planters, the Government, and everybody else forget that malaria costs much more money. Look at all the sickness which is caused by it; look at the invaliding, and not only the money it costs, but the misery it produces. Then put on the other side the cost of reducing it.

Sir Malcolm Watson has done a triumphant piece of work for the British Empire, equalling that done by Gorgas for the United States, and I cordially congratulate him on his lecture to-night.

A Cancer Enquiry Card.

As our readers will remember, the question of the rarity or otherwise of cancer in Indian patients was recently raised in our columns by Lieutenant-Colonel H. Halliday, I.M.S., and at the time we suggested that if information on the subject were to be collected, it should be done so on a systematic basis, and some standard form of enquiry card used. We have now received from Colonel Halliday the following suggested enquiry card in this connection, filled in with the history of a hypothetical case:—

Cancer Enquiry Card:—

Name	Radha Kishen.
Age	69.
Sex	M.
Caste or Race	Hindu.
Occupation	Clerk.
Literate	Yes.
Residence (Village or Town). State years of residence	Jullundur city (since leaving school).
History of Chronic Irritation. (Pan, Kangri, soot, tar, etc.)	Pan chewer, 50 years.
Constipation. (Average number of stools daily.)	Severe since childhood. Bowels open every 3 days.
Gastro-Intestinal History. (Gastric ulcer, appendicitis, gall-stones, etc.)	Gangrenous appendix removed in 1916.
Clinical diagnosis of the growth	Epithelioma.
Site	Tongue.
Operation	Hemisection.
Pathological Report. (State name of pathologist and laboratory in which examined.)	Epithelioma. Prof. of Pathology, K. E. Hospital, Lahore.
Lymphatic Involvement	Yes. Sublingual.
Subsequent History	Died of hæmorrhage from cervical recurrence.

The Silhouette Radiogram.

We recently had the pleasure of reviewing the very fine atlas of silhouette radiograms of the bones and joints by Mr. A. P. Bertwistle, M.B., Ch.B. (Leeds), Resident Surgical Officer, General Infirmary, Leeds. Mr. Bertwistle sends us the following short note on the process, from the *Canadian Medical Association Journal*, August, 1924, and the very remarkable series of silhouette

radiograms from the *Lancet*, 1923, II, p. 783, which we reproduce with due acknowledgments to both journals. As our readers will see, the method is a vast improvement on the ordinary radiogram.

"It is a striking fact that whereas a radiographic negative clearly indicates the outline of the flesh, a print from such a negative fails in this particular. The result of this loss is that the print loses much of its value; it is something apart from clinical diagnosis, and gives no evidence of the points on which the clinical diagnosis was made.

Some text-books seek to indicate soft parts by over-exposing the prints, but they do so at the expense of

the skin, which is always apparent, is scratched with a mounted needle. When the negative is printed the margin, thus outlined, shows as a black line. The background is now filled in with Indian ink, and the silhouette radiograph is complete.

This method of printing enables one to form an idea of what the radiograph findings will be, when certain deformities are next met with. A silhouette radiograph of a dislocated shoulder reveals the loss of the deltoid fulness—the basis of Hamilton's ruler test—and increased axillary girth—(Calloway's test). When such alterations in the shoulder are next encountered it will be easy to visualize an empty glenoid fossa, and

III.

FIG. I.—Caries of thumb. Note (1) Bone: disorganization of distal part of terminal phalanx, with abscess cavity in which is sequestrum; and (2) Skin: bulbous end, the result of periosteal whitlow.

FIG. II.—Rickets showing characteristic contour and accompanying bony lesion. (Stage I of method.)

FIG. III.—Callus of ulna.

IV.

V.

VI.

FIG. IV.—Colles' fracture. Note (1) Bone: impaction of radius so that styloids of radius and ulna are on the same level; and (2) Skin: radial deviation.

FIG. V.—Normal wrist-joint.

FIG. VI.—Fracture of patella. Note (1) Bone: transverse fracture due to muscular effort, and upward tilting of lower fragment; (2) Skin: swelling of joint and depression over site of fracture.

the bony definition. A radiograph is intended to show bones with the greatest possible distinctness.

The silhouette* radiograph was evolved with the object of at once correlating the clinical findings with those of the roentgen rays. The ordinary radiograph is largely a shadow photograph of bone; the silhouette radiograph is one of flesh and bone. The method is simple in the extreme. A negative is held up to the light, or placed in an illuminator, and the margin of

the head of the humerus lying beneath the coracoid process. The bulbous finger tip, and spindle fingers, are suggestive of a periosteal whitlow, and tuberculous dactylitis respectively. In an injury to the knee, loss of extension, and a transverse depression over the site of the patella make a fracture of that bone highly probable. The loss of the gentle sweep of the shoulder points to a dislocated, or fractured clavicle. On seeing

a hand radially deviated, and displaced backwards in the "dinner fork" position, it is easy to visualize that the underlying cause is an impacted fracture of the radius, with backward displacement of its lower end. The "wave deformity" of the forearm, with dorsal trough and ventral crest can only mean a "greenstick" fracture of radius and ulna.

Thus the underlying cause of any swelling is readily ascertained. Where the swelling is due to bone disease it is intimately associated with that disease. Where, on the other hand, the bones are normal the cause must be sought elsewhere.

The geography of sinuses injected with bismuth, or into which a probe has been passed can be readily studied. Foreign bodies instead of appearing "in space" show their proper relations as regards depth and position.

By means of the silhouette radiograph it is possible to confirm the impressions formed by palpation. In a dislocated elbow it is easy to see how the hard mass anteriorly, and the loss of resistance posteriorly, are caused.

Muscular wasting is an important sign of bone tuberculosis. In the selecting of many plates considerable help was given by this feature. Malignant, or rachitic disease is not so accompanied, nor is osteomyelitis in which condition irregularities due to sinuses are often seen. The adequacy, or otherwise of the coverings of a stump is apparent. All this is lost in the simple radiograph.

An important asset of the silhouette radiograph is the manner in which it shows the position of the limb at the time of the screening. In consequence of the risk of loss and breakage it is not always advisable to send negatives by post. I would suggest that if the skin outline were scratched on the negative before a print was made, the practitioner would at once recognize its increased usefulness.

The addition of the silhouette should aid diagnosis in that it imparts a much needed reality to the radiograph."

Blastomycosis in the Duars.

(Abstract of a paper read by Capt. P. Ganguli, B.A., D.R.M. (Bengal), at the Medical Research Section, Indian Science Congress, January, 1925.)

THIS is a very common affection in the tea-gardens of the Duars. It occurs chiefly among the coolies working in the gardens situated between Bhutan and Cooch Behar. It is prevalent during the rainy season, causing tremendous loss to the gardens in the collecting season. Generally 10 to 40 per cent. of the coolies become affected, and the cure takes a very long time—from 6 months to a year or more. Like Naga sore, trauma is one of the principal factors in the causation of this disease. In some cases it appears as a small ulcer from the beginning, but in the majority of cases it begins as an elevated warty growth which ultimately develops into an ulcer. In a few cases, the warty growths remain dormant for some time and undergo spontaneous absorption for the time being, only to recur as numerous warts round the cicatrices, which ultimately ulcerate. After some time they take on a gummatous appearance and the surrounding parts become oedematous.

Scrapings from these warts showed yeast cells and culture in saccharose agar was successful.

Reviews.

THE MEDICAL YEAR BOOK AND CLASSIFIED DIRECTORY, 1925. London: William Heinemann (Medical Books), Ltd. Pp. 596. Price 12s. 6d. net.

THIS little handbook contains a wonderful digest of information. It is edited by Mr. C. R. Hewitt, late Librarian of the Royal Society of Medicine, and Assistant Librarian, Royal College of Surgeons. Practically speaking, it is a medical "Whitaker's Almanac," replete with useful and miscellaneous information with regard to the medical profession in England, and a book of reference essential in every large medical library.

Included within its covers are a diary of meetings of medical societies for 1925; a review of the present position of the profession of medicine, medical education and registration; an account of the London Hospitals and Schools, Metropolitan Hospitals, and a list of London consultants and specialists; an account of the Provincial Universities, Hospitals, specialists and consultants; parliamentary and medico-legal news; information regarding the Royal Army Medical, and Naval Medical and other services; of medical and benevolent societies; of nursing associations, and of medical periodicals, works and pamphlets; together with an obituary for 1924. There can be few questions with reference to the medical profession in the British Isles which cannot be answered on reference to this very complete volume. It has a very complete index, and the general practitioner who wishes to answer any of many miscellaneous questions, from the selection of a consultant in tropical diseases at Home to whom to send a patient, to that of a medical school to which to send his son for professional education, will find within it a mine of useful information and instruction.

A TEXT-BOOK OF PATHOLOGY.—By W. G. MacCallum, Professor of Pathology and Bacteriology, the John Hopkins University. 3rd, 1924, edition. 8vo; 1162 pp.; 575 Illustrations, including many coloured plates. Philadelphia & London: W. B. Saunders Co. Price 45s. net.

MACCALLUM'S "Pathology" is perhaps the best of all the well-known standard text-books on this subject, both for the student and for the general practitioner. Its author is one who has a world-wide reputation as a morbid histologist, and there is hardly any other general text-book on pathology which is so detailed, so splendidly illustrated, and so valuable as his with regard to morbid histology. "Pathology and clinical medicine" he writes, "are after all the same thing viewed from slightly different angles." But from what different angles; since the first strives to explain and to lay the foundations for the second! Ultimately most diseases depend upon injury to or disturbance of function of the different tissues, and it is especially from this point of view that the book has been written. Hæmatology, bacteriology, and the much vexed question of the fundamentals of immunity, the author does well to refer to but briefly; his intention is to describe the macroscopical and microscopical changes associated with different diseases, and in this aim he has succeeded admirably. As his main thesis is the changes consequent upon injury to or disease of the tissues, the pathology of tumours occupies a special and separate section.

In this third edition much has been re-written or revised. The sections on rickets, diabetes and insulin, epidemic encephalitis and typhus, for instance. The illustrations are very good indeed, whilst the numerous colour plates lend an added value to the volume and teach more than would pages of text. Tropical diseases do not receive special attention in the volume, but what information there is, is accurate. Recent work

on the endocrine glands receives full recognition, and is well illustrated.

As a handbook of general pathology for the student and general practitioner, MacCallum's is an exceptionally detailed, well written and well published work. It has for many years been a favourite book for consultation in the larger pathological laboratories, and for the student. There are few books which are its equal in this special field.

PATHOLOGICAL TECHNIQUE; A PRACTICAL MANUAL FOR WORKERS IN PATHOLOGICAL HISTOLOGY AND BACTERIOLOGY.—By Frank Burr Mallory, A.M., M.D., Pathologist, Boston City Hospital; and James H. Wright, A.M., M.D., S.D., Pathologist, Massachusetts General Hospital. 8th edition. Philadelphia & London: W. B. Saunders Co., 1924. Pp. 666. Illustrations 180. Price 32s. 6d. net.

"MALLORY AND WRIGHT" is a staunch and well-trying friend of the laboratory worker and clinician, and in its own particular sphere is quite unique. The authors' aim is not the production of some standard text-book on morbid histology, or a treatise on bacteriology, but a work of practical value to the student, the laboratory worker, and the general practitioner. Given the preliminary autopsy on a patient who has died,—full and explicit details for which are given in a special chapter—and a full case-history and details of the post-mortem findings, the clinical pathologist is still far from having finished his task. He has next to study the morbid histology of the organs removed, to carry out bacteriological and protozoological enquiries. And, in assisting him in such a task, we know of no other standard book which so admirably meets the requirements of the laboratory worker. "The solution of the problem often requires the highest skill in post-mortem, bacteriological and histological technique, but in its solution lies the fascination of pathological work." Thus it will be seen that the scope of this well-known work is both comprehensive and yet detailed; gross morbid anatomy may begin the solution of the problem, but before it is fully solved bacteriological, histological and even biochemical methods may be requisite. And in its presentation of such methods "Mallory and Wright" is unique. The bacteriological micro-photographs alone constitute a very fine feature of the work, as they have always done.

The various sections of the book deal with histological methods,—a section which is full, authoritative, detailed and very valuable; bacteriology and mycology, animal parasites, blood examinations, serological technique, and detailed instructions for post-mortem examinations. The present, 8th edition, has been largely re-written; Dr. R. N. Nye having re-written the five sections devoted to bacteriology and serum diagnoses; Dr. T. E. Buckman that on technique of examination and interpretation of results; Dr. S. T. Orton that on the central nervous system; Dr. J. B. Ayer and Miss I. R. Cockrill that on examination of the cerebro-spinal fluid; and Dr. D. Munro that on the method of opening the skull in the new-born. Other sections on pigments, fats and lipoids, and museum specimen preparation have been largely re-written. In brief the book is even better value than ever before; one which the laboratory worker will find unusually comprehensive and authoritative in scope; whilst at the same time being a valuable *vade mecum* for the student and general practitioner.

HANDBOOK OF CONDENSED DIFFERENTIAL DIAGNOSTICS AND URINE EXAMINATIONS.—By Gurdit Singh, L.M.F. (Bengal). Lahore: Khosla Printing Works, 1924. Pp. 141. Price Rs. 4.

THIS little handbook will be one welcomed by medical students in India. Whilst it lays no claim to originality, it is yet useful in presenting in tabular form the differential diagnoses between diseases which may simulate one another; in impressing on the student the essential points in the diagnosis of different common diseases,

and in summarising information from larger treatises. Various tabular sections deal with the differential diagnosis of the infectious eruptive diseases; of the comatose states; of acute eye affections; of acute inflammations of the throat, of the breast and the chest. Diseases of the lungs are next fully dealt with, again in tabular form; followed by sections on the differential diagnosis of conditions associated with acute epigastric pain and with hepatic symptoms. The diarrhoeas, renal and testicular affections, chancres and the different types of dysmenorrhoea are then dealt with, followed by tables dealing with the diseases causing pain in the lower abdomen and pelvis and in the joints. A very full section on urine analysis, and the interpretation of its results, is finally followed by a full index. The general get up and binding of the volume are good.

Such a book may be of special value as a cram book for students preparing for examination, but it is also something more; a useful and original digest of the larger and more detailed volumes, useful for reference for the general practitioner, and in its tabular form especially convenient for referring to. On the whole a book that we can recommend both to the student and to the general medical practitioner in this country. The author might, perhaps, have taken more account of those diseases most common in the tropics, but he has done his work well, and the book is a very useful one.

LANDMARKS AND SURFACE MARKINGS OF THE HUMAN BODY.—By L. Bathe Rawling, M.B., B.C. (Cantab.), F.R.C.S., Surgeon to St. Bartholomew's Hospital. Sixth Edition. Thirty-six illustrations. Pp. viii plus 98. H. K. Lewis & Co., Ltd.: London, 1924. Price 7s. 6d. net.

WE welcome the sixth edition of this excellent book on surface anatomy. All the important surface markings are particularly clearly described, and at the end of the book three appendices give the length of various passages, tubes, etc., weights of the more important organs, and the ossification, and epiphyses of the bones of the upper and lower extremities. There are five more illustrations in this edition than in its predecessor and generally speaking they are far clearer and more striking.

The only criticism we offer is that the new terminology, which is taught in India, finds no place in this book. Owing to its general excellence, small and handy size, and large, good type, we strongly recommend it for the use of students and general practitioners.

A MANUAL OF PRACTICAL CHEMISTRY FOR PUBLIC HEALTH STUDENTS.—By Alan W. Stewart, D.Sc., A.I.C. 2nd edition. London: John Bale, Sons & Danielsson, Ltd., 1924. Pp. 83. Price 5s.

THIS is the second edition of a small book which many students have found useful in preparing for the chemistry of Part I of the D. P. H. examination. It is intended as a bench book for easy reference during practical work and "not to replace the text books on public health chemistry." This disarms some obvious criticisms to which it might otherwise be open. Experience has shown that the book has proved useful and no doubt the new edition will find a ready sale. The practical methods given are described shortly and clearly, and as a rule accurately. There are one or two statements one would like to see put more correctly for the elementary student. Nowadays very few analysts adopt Clark's scale of hardness as the only one.

On p. 50 the "simple formula" for estimating the percentage deficient in fat is misleading. It takes no account of the reduction in the fat as the result of watering. The matter is not so "simple."

The difficulties in the analysis of sour milk are not indicated.

The Leffmann Beam modification of the Reichert-Wollny process is that now usually carried out, but is not described.

On p. 56 butyric, caproic, caprylic and capric acids are stated to be "volatile and soluble." This statement is open to objection, in fact is probably not true. The Polenske process is not mentioned. As we have stated, the book is a useful bench companion but is hardly complete enough and has a few mis-statements.

A HANDBOOK OF MIDWIFERY FOR MIDWIVES, MATERNITY NURSES AND OBSTETRIC DRESSERS, 6th Edition.—By Comyns Berkeley, M.A., M.C., M.D. (Cantab.), F.R.C.P. (Lond.), M.R.C.S. (Eng.). Cassell & Co., Ltd.: London, 1924. Pp. 578. Price 8s. net. Illustrated.

THE sixth edition of "A Handbook of Midwifery for Midwives, Maternity Nurses and Obstetric Nurses" by Dr. Comyns Berkeley is well up to the standard of its predecessors. It is extremely difficult to arrange a book of this nature so that the readers for whom it is meant do not have to wade through a maze of unnecessary material, and at the same time to present them with the essentials. This work appears to us to strike the happy medium. The paragraphs explaining what the doctor will do when the case goes beyond the ordinary powers of the midwife are particularly useful in this country, where the nurse may be many hours' journey away from the nearest doctor and where she may be called on to deal single handed with obstetrical emergencies.

The chapter on ante-natal work is excellent, as is also that on the care of infants. If we have any criticism to offer it would be that the table showing the height of the uterus at various periods of pregnancy is likely to give a wrong impression. We have never found the fundus uteri two inches above the symphysis at 4 weeks; and also the method of determining whether the arms are extended or not in a breech presentation—i.e., by estimating the distance of the angle of the scapula from the middle line—seems to us to be well calculated to lead to errors in diagnosis. However, those are small points.

The script is excellent and the illustrations well carried out. The fact that since the fifth edition appeared in 1920 there have been three reprints and a sixth edition recently testifies to the great practical value and popularity of the work.

DYSPEPSIA: ITS VARIETIES AND TREATMENT.—By W. Soltau Fenwick, M.D., B.S. (Lond.). 2nd Edition. London and Philadelphia, W. B. Saunders Co., Ltd., 1924. Pp. 515. Price 24s. net.

THE original plan of this book was formed thirty years ago, but the present volume is far different from the one originally contemplated by the author.

There is no branch of medicine which is more difficult than dyspepsia, and it is likely that most practitioners will welcome the help which Dr. Fenwick offers to them in this volume. The author has had a vast experience in dealing with dyspepsia, and his methods of treatment have the great merits of success and popularity.

Dyspepsia in India is even more difficult than dyspepsia in European countries and up till now no serious attempt has been made to write a connected account of the subject. Dr. Soltau Fenwick has written three other books on diseases of the stomach, it is perhaps a pity that he did not attempt to combine all his work on gastric disorders in a single volume.

The advanced practitioner and the teacher of medicine will certainly find help and inspiration from this book.

ESSAYS AND ADDRESSES ON DIGESTIVE AND NERVOUS DISEASES AND ON ADDISON'S ANÆMIA AND ASTHMA.—By Arthur F. Hurst, M.A., M.D. (Oxon.), F.R.C.P. London: William Heinemann (Medical Books), Ltd., 1924. Demy 8vo., pp. vii plus 306, 15 plates, 50 figures. Price 21s. net.

This is a fine collection of essays and addresses by Dr. A. F. Hurst; the contents have in many instances been published in various British journals. It will be very useful to students and practitioners, not only

because it brings together the subjects in an orderly whole, but also because the articles have been revised and expanded by the author in the light of recent researches. The titles and presentations of the subjects are novel, the chapters on "sins and sorrows of the colon," ulcerative colitis, the nervous disorders of the stomach and intestines, appendicular dyspepsia, gall-bladder diseases, hysterical elements in organic diseases and asthma cover a wide field, and are written in a clear and illuminating style. In Addison's anæmia the author found achylia gastrica a constant factor and the cause is believed to be due to infection by *Streptococcus longus* from the mouth, which becomes more so because of the absence of normal

juice. The severity of the anæmia and the nervous symptoms are held to depend on the relative production of hæmolytic and neurotoxic bodies. Team work in the diagnosis of all the diseases dealt with is absolutely essential and the author strives to impress this truth in every chapter. There is no physician or surgeon who will not read this volume with profit and interest.

AN INTRODUCTION TO THE PRACTICE OF MEDICINE.—By William Boxwell, M.D. (Dub.), F.R.C.P.S. and F. C. Purser, M.D. (Dub.), F.R.C.P.I. Dublin, Talbot Press, Ltd., 1924. Pp. xv and 805. Price 30s. net.

At last someone has had the courage to publish a text-book of medicine which is really suitable for the average medical student. This excellent little book by Dr. Boxwell and Dr. Purser of Dublin contains about 900 pages, printed in a good sized type with liberal margins for the student's own notes. The substance of the book is by no means condensed and an attempt has been made to eliminate everything that is not of first class importance to the student. A book on these lines if specially written for Indian students would be of the greatest value.

Even as it stands Boxwell and Purser's book, if used in conjunction with a small manual of the special diseases of India, would fill the bill much better than any of the more elaborate text-books.

The intention of the authors is to give in a brief but explicit manner an account of what every young doctor must know about medical diseases. The book is far from being a complete account of medical diseases. It is still farther from being a book of reference, but it is just because it makes no pretence at being either of these things that it is so valuable. A specially useful feature of the volume is that it is written from the standpoint of the practitioner who has not the resources of special laboratories at his disposal, the tests and methods of examination which are described can be carried out by any doctor with a properly equipped consulting room.

The book is the product of men of mature and sound judgment who are capable of expressing themselves in an attractive and striking manner.

We shall be much interested to see whether the book is a success; from what has been said it is clear that it ought to be successful, but that is quite a different matter.

HANDBUCH DER TROPENKRANKHEITEN.—Prof. Carl Menze. Vol. III. Third Edition, 1924. Malaria and Blackwater Fever, by Prof. Dr. Hans Ziemann. Leipzig: Johann Ambrosius. Pp. 592. 152 illustrations and 7 coloured plates. Price 40 gold marks.

THIS very important volume is the most complete work in existence on malaria. It contains a complete summary of existing knowledge on malaria. The greater part of the book consists of a statement of the important facts in connection with malaria; the views of the numerous workers are stated in clear terms and a very voluminous list of the articles on each branch of the subject is given. The book is a veritable encyclopædia of malaria, but at the same time the author gives a critical summary in which his own views are stated.

The student will find himself rather bewildered at times by the very completeness of the book which is the result of years of painstaking work. It is especially as a book of reference that it has its greatest value and it is amazing that the Germans should still lead the world in the production of monumental treatises on tropical diseases when we consider how greatly their sphere of influence in the tropics has been contracted. As the author points out, malaria is no longer a tropical disease, it has spread with alarming rapidity in Russia and in other parts of Europe, and in spite of the completeness of our knowledge of its prevention it is still the greatest of the world's diseases. To review the book would necessitate a survey of the entire subject of malaria. There are some respects in which the book is not so helpful as in others; the dangers of intramuscular injections are not sufficiently emphasized, desensitization is not fully described, and too much space is occupied with the description of views and methods of minor importance. We must content ourselves with the statement that there is no aspect of the disease which is not dealt with in detail and that the book is indispensable to every specialist in malaria. The only pity is that there is not an English translation of a work of such completeness and importance. Even for those who have no knowledge of German the excellent tables and illustrations in themselves make the book a valuable acquisition. It should certainly find a place in every large medical library in India.

MODERN METHODS OF TREATMENT.—By Logan Glendenning, M.D. St. Louis: C. V. Mosby Co., 1924. Pp. 692. Price \$9.00.

THE chief feature of this book is that it deals with dull subjects in such a way as to make them exceedingly interesting. A general account of drugs is usually dry to a degree, but by confining his attention to the great drugs and by adopting the historical method of describing how they have come to occupy their present position the author has succeeded in making this section of the work very readable.

In the general account of the important drugs the author gives detailed instructions for their administration. Vaccines are dealt with in a very critical manner and only a few receive the hall mark of approval, these are the vaccines ordinarily used in the treatment of *B. coli* infections, acne, chronic bronchitis, cholecystitis and certain forms of tuberculosis.

The vaccines which are so commonly used in the prevention and cure of common colds are denounced as being worthless. Dietetics, hydrotherapy, climate, heliotherapy, massage, radiotherapy and psychotherapy are clearly and fully dealt with.

Various miscellaneous procedures such as blood transfusion, lumbar puncture, artificial pneumothorax, etc., are described in detail, so that even the general practitioner who follows the directions intelligently ought to be able to carry them out. About one-third of the volume is given up to the description of the treatment of particular diseases. This section is simple, clear and precise, perhaps at times a trifle too dogmatic as for example in the section on pneumonia in which the only drug treatment specified is ten drops of tincture of digitalis every four hours.

The general practitioner will be disappointed in finding no prescriptions for chronic bronchitis, this is a condition in which the patient demands medicine and in which medicine is often of great service to him. Other items might be criticised, but taking it on the whole the book is one which we can heartily recommend to every practitioner: it will not take the place of such a book as Whitla's "Dictionary of Treatment," but it will form an excellent complementary volume.

FUNDAMENTALS OF HUMAN PHYSIOLOGY.—By R. G. Pearce, B.A., M.D. and J. J. R. Macleod, M.B., F.R.S. Third Edition. St. Louis: C. V. Mosby Co., 1924. Pp. 349. Price, \$3.50.

THIS is an elementary text-book which gives a good general outline of the main principles of human

physiology. It might be read with profit by students who are entering on the study of physiology, but it does not contain enough to satisfy the requirements of any of the university examinations in medicine. The accounts of the vitamins and of the functions of the skin are insufficient even for a book of such small size, but on the whole the book can be heartily recommended to the student of elementary physiology.

A MANUAL OF DISEASES OF THE EYE.—By C. H. May, M.D. (New York), and C. Worth, F.R.C.S. (Eng.) Fifth Edition. London: Baillière, Tindal & Cox, 1924. Pp. viii + 460. Plates 22, coloured. Price 15s. net. Figs. 337.

THIS excellent book, now in its fifth English and thirteenth American editions, maintains its position as the most popular student's book on ophthalmology. It has been translated into Spanish, French, Italian, Dutch, German, Japanese and Chinese.

Looking through it, the large number of good illustrations both coloured and otherwise, and the careful way in which it has been kept up to date, strike one at once. At the same time the book is not too long and cumbersome for the ordinary medical student or general practitioner.

REFRACTION OF THE EYE.—By E. Clarke, M.D., F.R.C.S. Fifth Edition. London: Baillière, Tindal & Cox, 1924. Pp. iv + 251. Figs. 98. Price 8s. 6d. net.

THIS new edition of an excellent text-book has been re-written and brought up to date, especially with a view to the requirements of candidates for the D.O.M.S. examination. As before, the nature and results of "eye strain" are given great prominence, and the illustrative cases at the end are of great value to all students of this subject. The changes are not very great, and the size of the book is not materially increased by them, but they are of a very useful and practical character, and the book continues to be the best English book on this subject.

A POCKET BOOK OF OPHTHALMOLOGY.—By A. J. Ballantyne, M.D., F.R.F.P.S. (Glas.) Second Edition. Edinburgh: E. and S. Livingstone, 1924. Price 6s. net. Pp. 144.

THIS small book is intended for use by students attending lectures and clinical teaching in ophthalmology and is interleaved for note taking with blank paper. In scope it covers in a brief way the whole subject; but the absence of any illustrations, and the extreme brevity of its pathology render it unsuitable for students, except in connection with a good course of lectures and clinical demonstrations, when it should be very useful.

Correspondence.

PUBLIC HEALTH IN MADRAS PRESIDENCY.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the paragraphs on "Hygiene and Public Health" on pp. 17 and 18 of the supplement issued with the February number of the *Indian Medical Gazette*, entitled "The Indian Medical Year, 1924," and particularly in connection with the statement that "Bengal has given the lead to other Provinces in the matter of utilising local self-governing bodies in the prevention of disease," I should like to draw the attention of your readers to the fact that in Madras Presidency, as early as October 1921, orders were issued regarding the formation of District Health Committees in each district (*vide* G. O. No. 1354-A. P. H., dated 19th October, 1921). A District Health Scheme, involving the appointment of a District Health Officer for each district, was introduced as an experimental measure in five districts in February 1922 (*vide* G. O. No. 165-P. H., dated 1st February, 1922), and a month or two later (*vide* G. O. No. 1096 L. & M., dated 21st

June, 1922, and No. 950-A. P. H., dated 6th July, 1922), Government ordered the old Provincial Cholera Parties to be disbanded and utilised the Sanitary Inspectors in these parties for providing a staff of trained Health Inspectors to work under the District Health Officers. This experimental scheme proved a complete success, and by G. O. No. 535-P. H., dated 27th March, 1923, a complete District Health Service was introduced with a District Health Officer and a number of trained Health Inspectors, varying from 8 to 14 in number, in every district in the Presidency. The experience of the last two years shows that the scheme has not only given a great stimulus to local public health endeavours, but has been of particular advantage in the prevention of epidemics arising from the large numbers of religious festivals which take place all over Southern India. Further details can be found in the Annual Reports of the Director of Public Health, Madras for the years 1921, 1922 and 1923, but I should be obliged if you would find space in your columns for this letter, so that any erroneous impression that may have been gathered might be removed. Since the days of Colonel King, I.M.S., it is perhaps not too much to say that Madras has always given the lead to the rest of India in matters sanitary.—Yours, etc.,

A. J. H. RUSSELL, M.A., M.D., D.P.H.,

MAJOR, I.M.S.,

Director of Public Health, Madras Presidency.

MEDICAL RELIEF IN RURAL AREAS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Dr. Nag's letter on the above subject in your issue for last December, though valuable, contains a suggestion therein to grant licenses to practice to unqualified allopathic practitioners,—a suggestion which hardly deserves any consideration at the present time, when hundreds of qualified medical men are turned out twice yearly by the medical colleges and schools in each Presidency.

Many of the newly qualified men, on finding the field overcrowded in the big cities, select good centres in rural areas for practice, where the field is undoubtedly great. But they find that the field is monopolised already by the unqualified, particularly allopathic practitioners, and above all by men who have served only as compounders for some little time to qualified medical men or in charitable dispensaries. The *mofussil* people have no idea at all as to the courses of study undergone, and the time and money spent by the qualified man in obtaining his qualifications. They think equally highly of any man, whether M.B., B.S.; L.M.S.; L.C.P.S.; or merely compounder, who manages to keep his dispensary crowded. Further, the unqualified practitioner, who is usually a compounder from the same locality, knows the local people well, and creates a favourable impression by the use of any means available, such as engaging touts and commission agents, winning over influential men of the locality of different castes and creeds, means which are beneath the dignity of a qualified man to employ. So much so, that, once his position is secure and his practice established, the unqualified quack undertakes cases of all sort for treatment, practises medicine, surgery and midwifery alike; freely uses all sorts of poisons, both those in and others without the British Pharmacopœia; gives intravenous injections, and manages to create an impression on the ignorant people of the locality that he is equal to or even better than the qualified man. His serious and even fatal mistakes pass unnoticed and unreprieved.

The public, finding that the qualified man does not fare well, gain a low opinion of his abilities, and his position is doubly unfortunate as he cannot resort to the unscrupulous means of the quack.

The present generation of *vaidyas* and *hakims* is not held in as high esteem by the public as were their forefathers, and they do not constitute serious rivals to the qualified medical man. Also they use for the most

part harmless indigenous drugs; their fees are very low, and they may even be of some benefit to the poor.

The Medical Registration Act, though imposing restrictions on those registered, does nothing to protect their interests and dignity. Under such circumstances many qualified medical men do not care to get themselves registered, whilst others are seriously thinking of withdrawing their names from a register which they find to be useless and impotent in their own interests. The rapidly growing number of qualified medical men in this country would be very grateful to you if you would raise your powerful voice (1) to induce Government to take urgent steps to protect the interests and dignity of the whole medical profession in this country; and (2) to appeal to the existing medical organisations in each Presidency and Province to start branches in the *mofussil* for the same purpose.—Yours, etc.,

N. F. DOCTOR, M.B., B.S.

NAWSARIJ,
5th January, 1925.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—On reading Dr. Nag's letter on medical relief in rural areas in your issue for last December, I recalled a tragedy which happened here last year. A *vaidya* was called in to attend a patient with menstrual disorder, and prescribed a mixture containing aconite; making the medicine up with his own hands. He was so proud of this mixture, which he had taken two or three days to prepare, that he insisted on several men in the locality tasting it and also took a considerable dose of it himself. An hour later symptoms of aconite poisoning set in. The *vaidya* died after some hours of suffering; the others recovered, as they had only had a small dose.

The deplorable conditions in *mofussil* villages could not be better illustrated than by the possibility of such cases occurring.—Yours, etc.,

S. D. NARAIN, L.M.P.

DHAKA, CHAMPARAN,
20th January, 1925.

CINCHONA FEBRIFUGE IN MALARIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In continuation of my letter on p. 643 of your issue for last December, regarding the therapeutic value of cinchona febrifuge in malaria, and the formula utilised by us, I have much pleasure in enclosing a short report by Sub-Assistant Surgeon Bankim Chandra Ganguly, one of the Sub-Assistant Surgeons employed on this railway, which is a gratifying testimony, not only to the value of the cinchona formula, but to the results which may be obtained by wise and loyal co-operation between the medical and operating staffs. The report runs as follows:—

"The formula has been used by the station staffs of all except two or three of the thirty stations concerned as a prophylactic against malaria, and generally with very satisfactory results. When taken on an empty stomach—especially in very debilitated conditions or in the very serious biliary type of malaria—the mixture may cause some uneasiness, nausea, giddiness or dizziness for the first day, until the magnesium sulphate in it opens the bowels. This can be avoided by relieving the bowels if constipated before the mixture is commenced. Most of the station-masters on this section have followed the directions which were published in the *Railway Gazette*.

At Sonarpur, the most notoriously malarious station in my section and where the Government of Bengal has started a malaria research laboratory under the Director of Public Health, we tried the mixture especially to test its efficacy. In this I was loyally helped by Sub-Assistant Surgeon R. N. Singha, of the Public Health Department, and by the station-master, R. N. Rakshit. Amongst over 300 railway population in this station I have had to attend to only two cases of fever, and there have been no more sick reports during the current

malaria season, which was otherwise one of the worst which I have ever experienced. I confidently believe, as do most of the staff who have used it, that the formula is superior to any other in prophylaxis, and superior to quinine in chronic cases of malaria fever as a remedial measure."—Yours, etc.,

T. H. BISHOP,
Chief Medical Officer,
Eastern Bengal Railway.

CALCUTTA,
27th January, 1925.

MERCUROCHROME IN MALARIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—There has been much on the new drug, Mercurochrome, during 1924 in the *Journal of the American Medical Association*. It has been generally used for its bactericidal effect in cases of septicæmia; also for the treatment of local infections and in tubercular sinuses. Recently I have come across an extract in a daily paper stating that Mercurochrome has been largely used by Dr. George H. Hooper of Tampico, Mexico, in the treatment of malaria, by injection, with what are stated to have been admirable results; cases of more than a year's duration having cleared up in 48 hours, and others resistant to quinine treatment, cured. I write to ask whether any of your numerous readers has had any experience of this drug in malaria, and as to its efficacy or otherwise in that disease.—Yours, etc.,

HARI CHARAN GUPTA.

MAKTAGACHA,
15th January, 1925.

GASTRO-JEJUNOSTOMY WITH A BAMBOO CLAMP.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—A male patient, aged about 35 years, a Kapu by caste, came to the London Mission Hospital, Kamalapuram, in July 1924, suffering from abdominal pain with discomfort and vomiting, of 6 or 7 years' duration. On examination of the case a diagnosis of pyloric stenosis was made and a date fixed for operation. As the equipment at this branch hospital was inadequate for the operation, a message was sent to the main hospital at Jammalamadugu asking for the loan of a three-bladed clamp as is usually used in gastro-jejunosomy. This failed to arrive in time, however, and a three-bladed clamp was improvised from bamboo, sterilised and used at the operation instead. The wound healed by first intention and the patient was discharged cured five weeks later.

There are probably many instances where the meagre equipment of branch hospitals could be temporarily supplemented with improvised instruments manufactured from bamboo.—Yours, etc.,

JOHN MOSES, L.M.P.

KAMALAPURAM, CUDDAPAH DIST.,
21st January, 1925.

THYROID EXTRACT IN THE TREATMENT OF NEPHRITIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Allow me to invite your attention to the following extract from the *Journal des Praticiens*, September 13, 1924, p. 601. I shall be very grateful if any of your numerous readers will kindly let me know their experience:—

"N. Fiessinger and H. Leboucher draw attention to a recent article by A. Guérin on the action of thyroid extract on the kidney, and make a valuable survey of recent literature referring to thyroid medication in nephritis, which was apparently first suggested by Heimsheimer in 1895. L. Thevenot has employed in the treatment of nephritis, not the ordinary thyroid extract, but thyrotoxin, the extract deprived of the toxic lipoids, using it in doses of 25 milligrammes, twice daily.

Epinger has insisted on the diuretic rôle of thyroid extract, and states that it is an ideal diuretic in renal affections, as it is an extra-renal diuretic, without any irritant effect upon the kidney; he employs it in doses of 0.03 grams daily of the dry extract of the gland, increasing the dose up to 1.2 or 1.8 grams daily. Campanacci has treated successfully three cases of renal anasarca with thyroid extract; details of these cases are given. Wenckebach has pointed out that in his experience cases of severe œdema resistant to diuretic treatment are cases of hypothyroidism. Drs. Fiessinger and Leboucher put forward the following conclusions: Thyroid extract, in doses of 0.03 to 1.5 grams or grs. $\frac{1}{2}$ to xx (of the dry extract) may be given four to six times in twenty-four hours in certain cases of nephritis with severe œdema, without hypertension, and with large amounts of albumen in the urine, when the patients are resistant to diuretic and dietary treatment; this method of treatment should be continued for three weeks and may give remarkable results."—Yours, etc.,

S. J. EAPEN, M.B., Ch.B. (Edin.).

SUNDRESWARA VILLAS,
ROYAPETTAH, MADRAS,
19th January, 1925.

PHARMASOL COLLO-CALCIUM.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—We have had forwarded to us from London copies of a letter sent you by Dr. Edward E. Prest, M.A., M.D., relative to our advertisement for Pharmasol Collo-Calcium.

We sincerely regret that the quotation from Dr. Prest's article was used without qualification in our advertisement. When the article was published the Anglo-French Drug Co., Ltd. were the sole export agents for Crookes' Collosols and were manufacturing them for export in the laboratories in France. This particular article was then filed for advertising purposes and, unfortunately, used in error in our advertisement for the new Pharmasol Collo-Calcium.—Yours, etc.,

THE ANGLO-FRENCH DRUG CO.,
(EASTERN), LTD.

YUSUF BUILDING,
CORNER CHURCHGATE STREET,
BOMBAY,
28th January, 1925.

VON HEYDEN 471.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the supplement included with the February issue of the *Indian Medical Gazette* and to the leading article in the *Gazette*, p. 73, *re kala-azar*, I shall be glad if you will kindly permit me to state I am the sole Indian representative of Messrs. Allen & Hanburys, Ltd., London, distributing agents for Von Heyden Compound 471. In the leading article you mention that the available supply of Von Heyden Compound 471 in India is insufficient to meet requirements. It will, however, interest medical men to know that Von Heyden 471 in ampoule form is now being imported by many of the leading chemists and medical storekeepers in Calcutta, and I myself have available, at this office, a large supply of this compound in 0.2 and 0.3 gramme ampoules, and arrangements have been made for further supplies to come forward regularly, so that medical men interested in the treatment of kala-azar should experience no difficulty in obtaining supplies. I should, therefore, esteem it a great favour if you would kindly give this information in the next issue of your journal, also that I shall be glad to forward a reprint of the article by Dr. L. E. Napier, M.R.C.S., L.R.C.P., which appeared in the *Indian Medical Gazette* in December 1923, to any medical man on application to me at Block E. 2, Clive Buildings, Calcutta.—Yours, etc.,

A. H. P. JENNINGS.

P. O. Box 2198, CALCUTTA,
13th February, 1925.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Colonel C. H. Bensley, I.M.S., to be Honorary Physician to the King *vice* Colonel Bhola Nauth, C.I.E., I.M.S., retired from 13th April 1924.

Lieutenant-Colonel R. P. Wilson, V.H.S., F.R.C.S., I.M.S., Professor of Surgery, Medical College, Calcutta, is appointed to officiate as Surgeon-General with the Government of Bengal, during the absence on leave of Major-General R. Heard, C.I.E., K.H.S., M.D., I.M.S.

The services of Lieutenant-Colonel E. C. Hodgson, D.S.O., I.M.S., an officer of the Medical Research Department, are placed at the disposal of the Government of Assam, with effect from the 26th December 1924, for appointment as Officiating Director of the Pasteur Institute, Shillong.

Lieutenant-Colonel A. H. Proctor, I.M.S., Civil Surgeon, Darjeeling, is appointed to act as Surgeon-Superintendent, Presidency General Hospital, Calcutta, *vice* Lieutenant-Colonel E. E. Waters, I.M.S., granted leave, or until further orders.

Lieutenant-Colonel A. C. MacGilchrist, M.D., I.M.S., is appointed to be Professor of Physiology, Medical College, Calcutta, *vice* Major J. A. Shorten, M.B., M.R.C.P., I.M.S.

The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's personal staff, with effect from the 17th December 1924:—

To be Honorary Surgeons.

Lieutenant-Colonel J. C. H. Leicester, M.D., F.R.C.S., F.R.C.P., I.M.S., *vice* Lieutenant-Colonel R. McCarrison, C.I.E., M.D., F.R.C.P., I.M.S., tenure expired.

Major J. B. Lapsley, M.C., I.M.S., Officer-in-Charge, Medical Store Depot, Madras, is appointed to officiate as Assistant Director-General, Indian Medical Service (Stores), *vice* Lieutenant-Colonel G. G. Hirst, I.M.S., granted leave.

Major J. D. Sandes, M.D., I.M.S., officiating Civil Surgeon, is transferred from Serampore to Hooghly, *vice* Lieutenant-Colonel E. O. Thurston, I.M.S., granted leave.

Major Sandes is also appointed to hold medical charge of the civil station of Serampore in addition to his own duties, until further orders.

Major P. F. Gow, D.S.O., I.M.S., Civil Surgeon of Rajshahi, is appointed to act as Second Professor of Midwifery, Medical College, Calcutta, *vice* Major V. B. Green-Armytage, I.M.S., granted leave or until further orders.

Major J. R. D. Webb, O.B.E., D.P.H., I.M.S., is appointed permanently as Health Officer, Simla, with effect from the 5th July 1923.

Captain F. R. Thornton, M.C., I.M.S., is appointed as Civil Surgeon, Coorg, with effect from the date on which he takes over charge from Major F. C. Fraser, I.M.S.

LEAVE.

Major-General R. Heard, C.I.E., K.H.S., M.D., I.M.S., Surgeon-General with the Government of Bengal, is granted 8 months' leave on average pay, with effect from the 13th January 1925.

Lieutenant-Colonel F. A. F. Barnardo, C.I.E., C.B.E., M.D., F.R.C.S.E., I.M.S., Principal and Professor of Medicine, Medical College, Calcutta, and First Physician, College Hospitals, is granted leave for two months and twenty-two days, with effect from the 25th March 1925 or from any subsequent date on which he may avail himself of it.

Lieutenant-Colonel E. E. Waters, M.D., M.R.C.P., I.M.S., Surgeon-Superintendent, Presidency General Hospital, Calcutta, is granted leave for eight months with effect from the 25th March 1925, or from any subsequent date on which he may avail himself of it.

Lieutenant-Colonel G. G. Hirst, I.M.S., Assistant Director-General, Indian Medical Service (Stores) is granted leave for four months and leave under military rules for the remaining period up to a maximum of 8 months in all, with effect from the 1st March 1925 or any subsequent date on which he may avail himself of it.

Major V. B. Green-Armytage, I.M.S., Second Professor of Midwifery, Medical College, Calcutta, is granted leave for seven months, with effect from the 15th March 1925 or from any subsequent date on which he may avail himself of it.

Major F. A. Barker, O.B.E., I.M.S., Senior Medical Officer, Port Blair, is granted leave for one month and fifteen days with effect from the 2nd March 1925, or such later date as he may avail himself of it, and on the expiry thereof his services are replaced at the disposal of the Government of Madras.

Major F. C. Fraser, I.M.S., Civil Surgeon, Coorg, is granted leave on average pay for eight months and in continuation leave on half average pay for ten months with effect from the 1st February 1925 or date of relief.

Captain J. C. De, I.M.S., has been granted by the High Commissioner for India leave for a further period of three months in extension of the combined leave granted to him.

RETIREMENT.

Lieutenant-Colonel A. E. Walter, O.B.E., I.M.S. Dated 1st February 1925.

RESIGNATIONS.

Captain Watts-Taylor, I.M.S. Dated 1st December 1924.

The undermentioned officers of the Indian Medical Service relinquished their acting or temporary ranks, subject to His Majesty's approval, with effect from the dates specified:—

Lieutenant-Colonel H. Boulton, C.B.E. Dated 16th December 1920.

Lieutenant-Colonel F. A. F. Barnardo, C.I.E., C.B.E. Dated 15th March 1920.

Major C. A. Godson, M.C. Dated 3rd January 1920.

Major H. R. B. Gibson. Dated 10th June 1920.

Major P. F. Wernicke (now F. P. Warwick, D.S.O.) Dated 2nd April 1920.

Major H. B. Scott, O.B.E. Dated 6th August 1920.

Major D. F. Murphy, M.C. Dated 28th July 1920.

Captain J. P. Huban, O.B.E. Dated 18th November 1920.

Captain J. B. Vaidya. Dated 12th May 1920.

Major G. McG. Millar, O.B.E. Dated 10th February 1919.

Major W. L. Harnett. Dated 22nd October 1921.

Major G. Holroyd. Dated 13th September 1920.

Major E. B. Munro, O.B.E. Dated 9th March 1921.

Major A. N. Dickson, M.C. Dated 6th December 1919.

Captain G. H. Mahony. Dated 5th September 1919.

Major A. G. Coullie. Dated 4th December 1919.

Major J. B. Hanafin, C.I.E. Dated 24th August 1919.

Major C. H. Fielding. Dated 22nd May 1920.

Major J. V. Macdonald, M.C. Dated 9th May 1919.

Major P. B. Bharucha, D.S.O., O.B.E. Dated 24th August 1920.

Major J. B. Hance, O.B.E. Dated 10th October 1919.

Captain R. Sweet, D.S.O. Dated 1st April 1921.

Captain W. R. Stewart. Dated 6th April 1919.

Captain K. R. Batra. Dated 4th May 1921.

Captain W. P. Hogg, D.S.O., M.C. Dated 10th August 1920.

Captain P. A. Dargan. Dated 31st December 1921.

NOTES.

OSMO-CALAMINE.

We have lately received from Messrs. Thomas Morson and Son, Ltd. a sample of one of their new products, "Osmo-Calamine." The uses of calamine, especially in connection with skin diseases, are so

numerous that the introduction of a very high grade of calamine, produced by an electro-osmotic process, is to be welcomed. Reports on examination of the product record that, when used in lotion form, Osmo-Calamine took nearly 24 hours to settle down from suspension, and that the precipitate was so light that it filled nearly half the bottle. Recently, supplies of raw material for the production of calamine have only been available with difficulty, and it is stated that much of the calamine on the market at present contains grit and other impurities. Morson's Osmo-Calamine is a most exceptionally fine powder, absolutely free from grit, and almost if not quite impalpable to the feel.

This product should prove exceptionally useful in the treatment of private cases of skin disease. At the time of writing (January, 1925), the "prickly-heat season" is off; but Morson's Osmo-Calamine is of such exceptionally fine and light texture that it will certainly be an interesting product with which to experiment in the treatment of that distressing complaint; whilst its uses in the various fields of therapy of skin diseases are obvious. The Indian agent is R. Krishnaswami, P. O. Box No. 500, Bombay.

AMBRIODIN.

"AMBRIODIN" was introduced some years ago by the Centaur Chemical Co., Bassishaw House, Basinghall Street, London, E.C.2, as a remedy for use in cases of epilepsy, neurasthenia, insomnia, whooping cough, asthma, and kindred complaints. Its composition, as stated by the *Lancet*, is ammonium bromide 5 grs., potassium iodide 1 gr., combined with a laxative, per tablet, and the formula is therefore a well known one, and one in general use. This product differs from many others in that it is not advertised to the public, but only to the medical profession, and that its composition on analysis agrees with its stated formula. The preparation has already been favourably reported on by the *Lancet*, the *Journal of Clinical Research*, and the *Prescriber*, so that any further recommendation is unnecessary. The tablets are put up in two forms; uncoated and soluble in water, and sugar-coated. The dose in a case of epilepsy is from 2 to 6 tablets twice daily, on rising in the morning and at bed-time, whilst an additional table of diet and general instructions is also given. The price varies from 8s. 6d. per bottle of 100 tablets to 78s. 6d. per bottle of 1,000 tablets.

This preparation is in general use in various institutions in Great Britain; it is stated that it has proved efficacious in cases of epilepsy where other remedies have apparently failed; whilst its formula is an unimpeachable one.

"TABLOID" HYPODERMIC INSULIN HYDROCHLORIDE (STERILE).

INSULIN has been successfully prepared by Messrs. Burroughs Wellcome & Co., as one of their well-known "Tabloid" products, each of which is equivalent to one average dose of 10 clinical units and which, when dissolved in 0.5 c.c. of sterile distilled water, is equivalent to an equal volume of standard insulin.

"Tabloid" Hypodermic Insulin Hydrochloride (Sterile) is prepared under conditions approved by the British Medical Research Council and has been submitted to exhaustive clinical tests. It has been found to be equal in all respects to standard insulin. The "Tabloid" product offers several advantages, not least of which are ensured sterility, stability and accuracy of dosage. They are convenient to administer, are readily portable, and may be dissolved within the syringe.

"Tabloid" Hypodermic Insulin Hydrochloride (Sterile) is issued in two packings: cartoons containing 10 products in one tube and cartoons of 10 tubes, each containing one product.

"MODERN ORGANO-THERAPY."

WE have received from Messrs. Burroughs, Wellcome & Co. a very attractive little handbook with the above title, which they will be glad to send to medical men (only) upon request. We are to-day just beginning to realise the extreme importance of endocrine functions in connection with tropical diseases. For instance the severe cachexia of malaria or of kala-azar is usually associated with both thyroid and suprarenal deficiency, and both glandular extracts are worth trial in such cases, especially in the "antimony-resistant" kala-azar case. Much of tropical debility is either dependent upon or associated with endocrine defect. As yet our knowledge on the subject is vague and scanty, but there can be no doubt of its importance in tropical medicine, and it is probable that the next few years will see much attention devoted to it.

In the meantime, the practitioner who wishes to prescribe endocrine glands in tropical practice must understand clearly the functions and actions of such glands and the indications for prescribing them; otherwise he will go in for shot-gun prescriptions which may do nothing but harm. In its simple and clear presentation of the facts underlying endocrine therapy as we know it to-day, this little handbook is very useful. It is also admirable for the restrained and careful manner of its compilation; it makes no exaggerated claims for organo-therapy; unlike other works on the same subject, it does not claim that the endocrine glands dominate personality, or that in the continued use of ovarian extract lies the secret of eternal youth and charm. We can cordially recommend a study of its pages to the medical profession in this country.

I. M. S. DINNER.

The Annual Indian Medical Service Dinner will be held in London at the Trocadero Restaurant on Wednesday, 17th June 1925. Officers wishing to attend should communicate with Colonel J. J. Pratt, 63, Addison Road, Kensington, London, W.C.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints of the literary pages of the "*Gazette*" gratis, if asked for at the time of submitting their manuscripts.

REPRINTS OF THE ARTICLE CONCERNED (ONLY), IN PLACE OF REPRINTS OF THE WHOLE OF THE LITERARY MATTER OF THE ISSUE, CAN BE SUPPLIED ON PAYMENT IF ASKED FOR AT TIME WHEN ARTICLE IS SENT IN. BUT AS THESE HAVE TO BE MADE UP SEPARATELY, THEY ARE NECESSARILY DELAYED.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE Editor, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

GIANT URTICARIA.

By HUGH W. ACTON,

MAJOR, I.M.S.,

Professor of Bacteriology and Pathology, School of Tropical Medicine and Hygiene, Central Avenue, Calcutta.

(Being a paper read at the Medical Section of the Asiatic Society of Bengal on the 11th February, 1925.)

THE disease "giant urticaria" was first described accurately by Quincke in 1882, and is sometimes called after him, Quincke's oedema. The original view, and the one commonly held by most dermatologists, is that the disease is due to a vasomotor neurosis, and in text books on skin diseases it is called an angio-neurotic oedema. The oftener I hear the term "neurosis" the less I like it and now avoid it, as the patient is and feels ill, whilst his medical adviser cannot find the root cause of the disease, and so labels his patient neurasthenic. During the last three years Major Chopra and myself have been working amongst these diseases due to a peculiar sensitiveness which individuals develop towards certain protein bases. In 1923 our first work dealt with the causation of asthma, and in 1924, "on some of the factors concerned in individual susceptibility." This year we have completed our observations on epidemic dropsy and beriberi. In the dermatological clinic one came across a number of cases of chronic urticaria and giant urticaria, where the same sensitiveness was seen towards certain foods. The various pressor bases which we have studied act in two ways; (a) on the involuntary muscular fibres, dilating or constricting the capillaries, and (b) increasing or diminishing the cell permeability of the endothelium. I will now show you the dermal test on myself, and demonstrate the action of trimethylamine, a volatile amine obtained from rotten herrings. The dermal test is done as follows:—The skin is sterilised by alcohol and with a knife lightly scraped short of bleeding, so as to open the prickle cell layer. A drop of the test solution is now placed on the scraped area. In a couple of minutes you will observe an area of hyperæmia, i.e., dilatation of the capillaries all round the site. In about five minutes when the solution is removed a definite wheal of urticaria will be produced, due to the increased permeability of the endothelium which allows an abnormal amount of lymph to exude into the tissues. The reason that I am sensitive to trimethylamine is that I am also sensitive to a volatile amine in sardines, as I can only eat this fish when they have been well fried, so as to get rid of the volatile amine. Now observe

the converse action produced by a drop of a 1 in 1000 solution of adrenalin hydrochloride, the vessels will be constricted, so that the zone of hyperæmia will first disappear, and gradually the wheal will be absorbed in a few minutes' time.

These bases have different iso-electric points; compare adrenalin which works best on the isolated uterus of a guinea-pig at a pH of 7.2, whilst trimethylamine works best at a pH of 8 (Acton and Chopra, 1925). We have further shown that the pH of the different tissues of the body varies. The brain and liver are the most acid organs in the body with a pH about 6. When the iso-electric point of the base coincides with that of the tissue, it exerts a maximum effect at that site, and so displays the phenomenon that is observed when drugs are selected by certain tissues. Some of these pressor bases functionate as ampholytes, i.e., acting at one time as an acid and at another time as a base; producing in one place constriction and diminished permeability, and at another relaxation and increased permeability. Thus adrenalin as you have seen constricts the skin vessels and diminishes their permeability, and probably acts as an acid; but in the vessels of voluntary muscles (tissues which are acid) it acts as a base causing dilatation and an increased permeability. In the production of urticaria, the same kind of effect is seen; there are bases that cause an increased permeability of the endothelium of the capillaries, so that wheals are produced in the skin;—the common nettle-rash or urticaria. On the other hand, certain bases cause the same effects, but only in the vessels under the deep fascia, producing a deep oedema,—the giant urticaria or Quincke's oedema,—which may involve a limb, or what is more serious the pharynx and larynx and cause death by oedema of the glottis. This catastrophe can fortunately be averted by the use of adrenalin and pituitrin.

The reason why I have selected this subject for my paper is that the disease is very much more common in India than in Europe, and it is very frequently mis-diagnosed as teno-synovitis, filarial lymphangitis, or chronic erysipelas. Quincke, Osler and others have drawn attention to the frequency with which these cases run in families, and it brings out the relationship between heredity and the occurrence of the endocrine defects that is observed in all these diseases due to the effects of pressor bases.

Definition.—We can now define giant urticaria or Quincke's oedema, as an urticaria produced under the deep fascia by certain bases derived from the food, which only show their effects in those individuals in whom the defence mechanism is low. This defect in the defence mechanism may be inherited or acquired.

Ætiology.—The disease is commoner amongst Europeans than Indians, but whether this is due to the fact that the cases amongst Indians are mis-diagnosed as filarial lymphangitis remains to

be further investigated by us. My attention to this disease amongst Indians was first drawn by two cases in which the scalp was involved by the œdema. Dr. Sunder Rao, who is investigating filariasis at our School, is carefully looking out for this possibility.

I am inclined to think that it is more common in Europeans owing to the depression of the endocrine functions by long residence in a climate like Calcutta. In Europeans the diagnosis is easier, as one is guided by the fact that at least 12 to 15 years' residence in an infected area is necessary before signs of lymphatic obstruction due to filariasis develop in them. There does not appear to be any difference in the sex distribution, as males are as often affected as females. In over half these cases a history was given that one of these food sensitisation diseases was present in the family, e.g., asthma, urticaria, etc. The age incidence is peculiar; the disease appears in very young children from 15 months to 2½ years, or in adults between the ages 30 to 45. In children the sensitiveness may be due to hereditary influences, but is more commonly due to living for too long a time on a whole milk diet, or when new foods are added to the diet. Both my cases in young children were due to milk, and what probably happens is that digestion in the stomach during early life is done by rennin, but later on in life when the pepsin and hydrochloric acid mechanism is fully developed the end-products of digestion are different at these two ages, and so sensitisation may develop. In adults, sensitiveness may occur from taking an excessive amount of the particular food; thus a Nepalese patient was free in Nepal where he only ate rice, but developed urticaria in Calcutta where he ate bread instead of rice, and we found that he was sensitive to wheat.

It may also develop from the infrequent use of a food, such as pork or beef. I have seen two cases due to beef in planters who have to live almost wholly on chicken when on their gardens. Again it may be seasonal, when it is associated with certain fruits, fishes, etc., which come into the market for only a short time during the year. At the age of 30 to 45 the internal defence mechanisms may be impaired, e.g., the functions of the liver by alcohol, the thyroid and adrenal functions by syphilis, alcohol, or climate and overwork. Three of my cases were *Entamœba histolytica* carriers. Acton and Knowles (1924) considered that occasionally the intestinal flora may be concerned in the reduction of some of the amino-acids of protein digestion into toxic bases, and in these three cases the liver was also enlarged owing to amœbic hepatitis. This disease is seen amongst sympatheticotonic individuals, and these people are very sensitive to adrenalin injections; small doses of *m.* iii to *m.* iv. injected intramuscularly will cause the heart to palpitate if given daily for 2 or 3 days.

Symptoms and signs.—The onset is usually sudden, coming on about 6 hours after the ingestion of the particular food, so that it is seen about 2 to 4 in the afternoon or at the same time at night, i.e., after the two principal meals of the day. The adrenal functions are at their lowest ebb during the early hours of the morning, and hence the frequency of the attacks coming on at this time. The arm is more commonly affected, and usually only one arm at a time; the limb is swollen, and feels heavy and the movements of the fingers are restricted. There is a good deal of pain and tenderness when the œdema occurs under dense fascia like the palms or scalp. As a rule there is no superficial urticaria or pitting of the skin on pressure, and sometimes the lymphatics draining the area may be dilated and congested, as in streptococcal cellulitis, but to a lesser extent. On the face, the main effect is seen in the lips and the eyelids, which are thick, swollen and puffy, and in case No. 5 of the Table there were large blebs containing sterile serum in the prickle cell layer. On the trunk, large plaques are seen under the deep fascia of the chest and abdomen and are usually associated with superficial urticaria. On the scalp, large plaques are formed on the top of the head or under the deep fascia of the occipital region; they are very painful and tender. On the legs, large plaques of solid œdema are seen and are often associated with an intensely irritable condition of the skin.—*Urticaria, ferox*—when the patients tear the skin of the legs by their scratching in order to relieve the irritation. The condition may last for a few hours or persist for weeks if due to some common food.

During these four years I have seen about 40 cases of this disease, and in Table I, I give the records of 20 cases that have been worked out fully during the last two years.

The signs of the disease are the solid œdema under the deep fascia; there is no enlargement of the lymphatic glands as is sometimes seen in filarial lymphangitis. Eosinophilia is more marked than in filariasis, counts varying from 20 to 60 per cent. of eosinophiles are not uncommon in the disease. On pressing the skin deeply with the thumb-nail and making a line on it, the white adrenalin line is seen. In superficial urticaria, wheals are sometimes produced, as in dermatographia. The dermal tests are much less marked in giant urticaria than in superficial urticaria.

Pathology.—We have seen that the disease is produced by certain pressor bases derived from the proteins of the food, which cause dilatation of the capillaries and an increase in the permeability of the endothelium lining the capillaries, so that hyperæmia and tissue œdema are produced as the result of their action. In giant urticaria these bases exert their main action on the vessels lying under the deep fascia thus giving rise to a solid œdema, but there is no pitting on pressure as the superficial vessels are not

usually affected, and the œdema is under the deep fascia. There are, therefore, three factors concerned in the disease.

(i) Pressor bases derived from the proteins, causing dilatation and increased permeability of the vessels under the deep fascia.

TABLE I.

No.	Race.	Sex.	Age.	Food Sensitiveness.	Duration.	Site of disease.
1	European.	Female.	1 $\frac{3}{4}$	Milk + + +	3 months.	Alternately arms and legs.
2	"	Male.	47	Aspirin.	One day : previous attack 3 months before.	Deep plaques on face and trunk.
3	"	Female.	24	Condensed Milk + +	One month.	Face, arms and legs.
4	"	Male.	43	<i>E. histolytica</i> carrier. Beef +++ Chicken ++ Eggs +	3 weeks.	Arms.
5	"	Female.	42	Pork + + +	4 attacks in 2 years : each lasted a week.	Face.
6	"	"	41	Eggs + + +	3 weeks.	Arm.
7	"	"	32	General Sensitiveness. Fish ++ Chicken ++ Eggs ++	4 weeks.	Arm.
8	"	"	33	Potato + + +	6 weeks ; also Scleroderma.	Arms, and plaques on the trunk.
9	"	Male.	47	Fowl group. Chicken + + +	10 days.	Arms.
10	"	"	43	Mutton + + +	6 months on and off.	Mastoid and occipital region.
11	"	"	35	General Sensitiveness. <i>E. histolytica</i> carrier.	2 months.	Scalp.
12	"	Female.	31	Tinned herrings + +	2 weeks.	Palms and fingers of both hands.
13	"	Male.	28	Milk + + +	On and off for 2 years.	Arms.
14	"	Female.	32	Wheat + + +	2 months.	Arms.
15	"	Male.	35	Chicken + + +	2 weeks.	Arms and trunk.
16	"	"	32	Tinned fish. Salmon + + + Lobster + + +	2 weeks : previous attack.	Legs.
17	Indian.	Female.	24	<i>E. histolytica</i> carrier.	2 months.	Scalp ; also horse asthma.
18	"	Male.	32	Fish, Hilsa +++ Rohu +++	3 months.	Arms and scalp.
19	European.	Male.	41	General Sensitiveness. Beef +++ Chicken ++	On and off for 6 months.	Plaques on abdomen.
20	"	Female.	33	Chicken + + +	2 months.	Arm.

(ii) A defect in the internal defence mechanism, due to diseases of the gut, liver or lowering of the endocrine functions.

(iii) Hyper-sensitiveness of the sympathetic nerves, a condition known as sympathicotonia.

In normal individuals, the effects of these bases are not seen, as they are dealt with by the various internal defence mechanisms.

Differential diagnosis largely depends upon the site involved by the œdema, especially if it is a true giant urticaria. Sometimes the lesions are of a mixed type when the superficial skin lesion, i.e., nettle-rash, readily reveals the nature of the disease. When the œdema affects the arm, usually it affects one arm only. I have seen it mistaken for (i) teno-synovitis. This case was diagnosed by a physician, then operated upon, and no pus was found; the case proved to be a giant urticaria due to eggs. (ii) Filarial lymphangitis in Europeans: the rule here is that at least 12 years' continuous residence in an infected locality is necessary before they develop lymphangitis, which would help in the diagnosis. In Indians the diagnosis is more difficult, eosinophilia is present in both diseases, but more marked in giant urticaria; the absence of microfilariae from the peripheral blood at night would not help, as at least 90 per cent. of the filarial lymphangitis cases have no microfilariae in their blood. The dermal tests help in these cases. (iii) When giant urticaria involves the face, the cases are usually diagnosed as chronic erysipelas; these cases are very puzzling if seen a few days after the attack, when blebs form and get infected by streptococci. Sometimes the lips only are involved, when one would have to exclude the various types of cheilitis, angular due to *Morax-Axenfeld's* bacillus, streptococcal, or syphilitic. On the legs it is more often of the plaque type, but when it involves both legs the cases have to be differentiated from epidemic dropsy and filarial lymphangitis. I have seen œdema of both legs, the case clinically resembled epidemic dropsy; in this case rice was eaten very occasionally, and the patient gave a very marked reaction to the dermal tests.

Prognosis.—The cure is certain if one can find the cause, and if it happens to be an unimportant food, eliminate it from the diet. The danger used to be death from œdema of the glottis. Thus Osler states that out of 141 persons in seven generations, 49 were affected, and 12 died of œdema; whilst Bullock (1909) states that out of 170 cases 39 died of œdema of the glottis. Now with the proper use of adrenalin and pituitrin this danger can be averted in most cases. The cases with general sensitiveness are more difficult to cure, and it means a lot of work to find the cause.

Treatment, General.—We can no longer regard the disease as a neurosis, it is due to some poison derived from the foodstuffs. The first thing we have to do is to find the cause and here the dermal tests are invaluable as this is

practically the only method to recognise the particular food, and then give the patient directions as to his diet. Recently I saw a case where the medical attendant advised the avoidance of all red meat; the patient had to live on chicken; the urticaria got much worse, and on testing him with these dermal reactions, I found he was very sensitive to chicken. Good food, the avoidance of too much alcohol, and often a change of climate if the patient is run-down will do a great deal to raise the power of the internal defence mechanism. When there is sensitiveness to three or four important foods, such as milk, eggs, wheat, etc., these should be restricted as much as possible during the course of treatment.

Specific Treatment.—Codd in 1917 pointed out the value of adrenalin in the disease; in 1924 Chopra and myself showed that adrenalin blocks the action of these bases and recently we have found that pituitrin helps the action of adrenalin. We have been giving $m \cdot ii$ of a 1 in 1000 solution of adrenalin hydrochloride intramuscularly every day for 4 or 5 days, then followed by suprarenalin gr. i. and ext. thyroideum siccum grs. $\frac{1}{4}$ twice a day on an empty stomach for 3 weeks. This treatment usually enables the patient to return with safety to the particular food to which he was sensitive to before treatment. If there is general sensitiveness, it is as well to examine the stools for *E. histolytica* cysts and to examine the size of the liver. Often emetine will cure the amœbic infection of the gut, and at the same time prevent the giant urticaria.

Bowels.—The stools should always be examined by microscopical and bacteriological methods. Salines and intestinal antiseptics like yatren may be necessary if the flora appears abnormal by the presence of yeasts, late lactose-fermentors and streptococcal colonies.

Local treatment by heat should be avoided, as it only increases the œdema; cold evaporating lotions like lotio calamine or lead lotion give the most relief.

OBSERVATIONS ON THE ANTI-DIABETIC PROPERTIES OF *CEPHALANDRA INDICA* (TELAKUCHA).

By R. N. CHOPRA, M.A., M.D., B.Ch. (Cantab.),

MAJOR, I.M.S.,

Professor of Pharmacology;

and

J. P. BOSE, M.B. (Cal.), F.C.S. (Lond.).

Mitra Research Scholar on Diabetes, Calcutta School of Tropical Medicine and Hygiene.

[Indigenous Drugs Series, No. 5 (1).]

Telakucha (*Cephalandra indica*) is a perennial creeping herb belonging to the natural order Cucurbitaceæ. It grows abundantly throughout India in a wild state and is known as *bimba* or *vimba* in Sanskrit, *kunderi-ki-bel* in Hindi, *tela-kucha* in Bengali, and *kabare-hindi* in Persian. The plant has tuberous roots, deep green leaves and a scarlet coloured fruit with a bitter taste. The Ayurvedic writers recommend the juice of its tuberous roots and leaves in diabetes; the leaves are also used by them in skin diseases. We investigated the anti-diabetic properties of this plant as its juice is often prescribed by medical practitioners in Bengal and wonderful results are ascribed to it.

Chemical Composition and Pharmacological Action.—The plant was analysed for us by Dr. Sudhamoy Ghosh, D.Sc., and Mr. Nihar Ranjan Chatterjee, M.Sc., to both of whom we are very grateful. The details of this work will be published in the *Indian Journal of Medical Research* for July 1925. Besides alkaloids, glucosides, etc., which commonly occur in plants, they also looked for bodies of the nature of hormones. Collip and his co-worker (1923) isolated from yeast, lettuce, onion tops and other plants, a substance called glucokinase which plays an important part in the plant sugar metabolism. Injection of this substance into rabbits causes a fall in the blood-sugar and produces convulsions in exactly the same way as does insulin, and these convulsions can be relieved by administration of glucose. Following a modification of the technique described by Collip, we isolated from this plant a body of the nature of an enzyme, a body of the nature of a hormone, and small traces of an alkaloid. The enzyme showed marked amylolytic properties, but subcutaneous injections in rabbits of these active principles showed no reduction whatsoever in the blood-sugar. The alkaloid was also found to be pharmacologically inert as regards its action on the circulation, respiration and alimentary system.

Clinical Tests.—We tried the fresh juice extracted from the plant in a series of six cases of diabetes in the Carmichael Hospital for Tropical Diseases, to see whether the claims made

regarding its anti-diabetic properties could be substantiated. The patients were selected at random and their carbohydrate intake was fixed and kept strictly under control. The total quantity of urine was collected and examined for the quantity of sugar excreted. The blood-sugar was examined and the patients were regularly weighed. After putting the patient on a strict diet, some time was allowed for the daily output of sugar to attain a constant level. Fresh *tela-kucha* juice was then given in doses of 1 to 2 ounces every morning on an empty stomach. The percentage of sugar in the urine, total sugar excretion, sugar value of the diet and blood-sugar were carefully investigated and recorded in each case.

Graph I.

In Graph I we have recorded the total excretion of sugar in 24 hours' urine of four patients under *tela-kucha*. It will be observed that the sugar excretion in all these cases practically showed no reduction. In cases Nos. II and IV, injection of insulin, just after *tela-kucha* was discontinued, resulted in the rapid fall of both blood and urinary sugar. It is a point worthy of note that case No. I whose average daily excretion of sugar was not more than 7 to 8 grammes only, remained quite unaffected by *tela-kucha*. As soon as the diet was reduced by 10 grammes the sugar entirely disappeared from the urine. Cases Nos. V and VI—not shown on the graph—were under *tela-kucha* treatment for 6 and 8 days, respectively, but showed no diminution in the sugar excretion whatsoever.

The good results claimed from the use of *tela-kucha* plant in cases of diabetes by other observers may be attributed in our opinion to the fact that a fairly large number of cases of so-called diabetes in this country are really cases of intermittent glycosuria, and these cases sometimes

improve without any medical interference. Very slight alterations in diet, as in case No. I, may cause disappearance of sugar from urine. In order to test the anti-diabetic properties of a drug the first thing to determine is the severity of the disease in a patient on whom it is going to be tried by glucose tolerance tests. The carbohydrate tolerance can thus be accurately estimated and then systematic and prolonged observations are made on the sugar in the blood and urine while the drug is being administered.

CONCLUSIONS.

1. The fresh juice extracted from *Cephalandra indica* (*telakucha*) has no sugar reducing effects when administered to patients suffering from diabetes.

2. The active principles of the plant, an amylolytic enzyme, a hormone, and a body of alkaloidal nature do not produce any reduction of blood-sugar when administered subcutaneously to rabbits.

RECENT ADVANCES IN THE OPERATIVE TREATMENT OF INTESTINAL STASIS.

By H. HALLILAY,
LIEUT.-COLONEL, I.M.S.,
Lahore.

As one who has been privileged to assist Sir Arbuthnot Lane at many of his operations for the relief of intestinal stasis during the past year, I am writing this brief note on the latest development of his surgical practice.

At the risk of repeating what I have no doubt is very well known to many of my readers, I must begin by a recapitulation of the pathology on which the treatment is based.

Owing to the rush and hurry of modern life, to the inhibitions imposed by civilisation, more and more people are yearly becoming the victims of chronic constipation. Probably one of the most powerful of the influences which brings this about, is the deliberate disregard of the calls of Nature and the systematic inhibition of the activity of the reflex mechanism of the lower bowel to suit the exigencies of school life.

The effluent of the small intestine is liquid on its entry into the cæcum, and the fæces of a physiologically efficient human being would be liquid or semi-liquid, as indeed they are with primitive or uncivilized peoples.

Rendle Short(1) quotes an interesting case in which the cæcum had prolapsed after an operation for appendicostomy in a case of chronic dysentery and everted itself through the wound so that the movements of the ileo-cæcal valve were plainly visible on the surface of the abdomen. It was noticed that directly after the

entry of food into the stomach the valve opened and the contents of the ileum were released into the cæcum in a series of jets and squirts by the peristalsis of the small bowel. The sphincter lay quite patulous for as long as half an hour after the end of the meal. It would appear to be a reasonable inference to assume that three liquid stools a day would be natural in those who eat three meals a day.

It is, however, a well ascertained fact in physiology that the rectum possesses great powers of absorbing water from the fæces, and that the longer the fæces are left in the large bowel the less water is left in them, until they may assume a stony hardness. It is obviously more difficult for the bowel to propel a solid cast of itself through its kinks and curves than it would be to release a liquid effluent. One of the first effects of this chronic over-loading of the bowel is experienced in that portion of the large intestine which is called the pelvic colon, and in consequence of the constant strain to which the suspensory mesentery of this loop of gut is subjected, bands of thickened tissue are developed along the outer leaf of the meso-sigmoid.

At first salutary in its effect, owing to the inevitable tendency of this tissue to contract, the mesentery of the sigmoid becomes shortened and deformed and the gut sharply kinked as a result of the opposition of the pull of the ligament to the unrelenting drag of gravitation. The last condition of the bowel is, therefore, worse than the first, and the attempts by Nature to remedy the morbid condition have ended by aggravating it. It is to this acquired band or rather to the result of its development that Sir Arbuthnot Lane, who was the first to point out its existence, gave the name of the "first and last kink." First, because it was the first in point of time to develop, and last because it is the kink situated on the lowest part of the large bowel.

It is in the direction of freeing this "first and last kink" that the latest development in the operative treatment of intestinal stasis has taken place. Sir Arbuthnot Lane regards this kink as the commencement of all the subsequent troubles which arise in an orderly sequence along the whole course of the alimentary tract. He calls it "a veritable Pandora's box which spells the failure of modern civilization."

The other main kinks which arise in the following sequence are:—at the splenic flexure; at the hepatic flexure; at the outer side of the cæcum and ascending colon; at the last few inches of the ileum, this kink may be brought about either by a "controlling appendix" or by a "Lane's band"; and finally at the duodeno-jejunal flexure and the gastro-hepatic omentum.

The effect of this first and last kink is to produce a condition of delay in the large intestine, and the longer this persists the further up the gut creep the effects of this rising tide of stasis. With the development of the ileal band (Lane's kink) or with the appearance of a

controlling appendix commences the water-logging of the small gut, consequent on the damming up of the ileal effluent and the consequent imposition of strain on the most vulnerable part of this sector of the gut, the gastro-duodenal flexure. A further block is thus established at this point, leading to choking of the duodenum and subsequently to the development of ulceration in the duodenum and stomach. A partial recognition of these facts by workers other than Sir Arbuthnot Lane confirms the frequent association of such conditions as duodenal ulcer and appendicitis. Sherren(2) found the appendix normal in 4 only out of 65 cases of duodenal ulcer, and in 5 only out of 41 cases of gastric ulcer.

It was left for Sir Arbuthnot Lane to evolve the comprehensive and logical formula which explains the problems presented by the protean complex which is gradually becoming recognised by medical men under the title of "intestinal stasis." Briefly, the series of changes which are initiated in the entire gastro-intestinal tract are as inevitable, and show as orderly a progression as those leading to the destruction of the secreting tissues of a floating kidney, in which the degree of motility is sufficient to allow kinking of the ureter and consequent damming back of urine and back pressure on the secreting tubules and the glomeruli.

Why people who are willing to admit that kinking of the ureter may produce back pressure on the kidney and subsequent damage to that organ, will deny with passionate energy that the most extreme degree of kinking of the bowel can in any way impede the passage of its effluent through it, I have never been able to understand. It is equally incomprehensible why those who will freely admit the presence of a mechanism in the body by which tissues and organs are able to adapt themselves to the effects of strain, will vehemently repudiate the possibility of a chronically overloaded mesentery crystallising its resistance to strain in the shape of adventitious bands of connective tissue along the lines through which that strain is constantly acting. Since in this stage of the controversy few will be found to deny the existence of the bands and kinks to which attention has been drawn by their discoverer, the opposition now attributes them to developmental defect. Even were they of developmental origin, a statement in support of which no one has ever advanced any proof, the medical attendant would still be faced with the necessity of treating them and the morbid states to which they give rise.

Lane's operation for the first and last kink.—Though the operation of colectomy is still performed by its inventor in certain cases, such as for cancer of the large intestine or extreme lengthening of the pelvic colon, he is not performing this operation as frequently as he used to do when on the staff of Guy's Hospital, as in private practice he does not see the end-results of intesti-

nal stasis in the extreme degree that was common in hospital practice.

In a very large proportion of cases excellent results are obtained by freeing the first and last kink alone, as this may be the principal cause of stasis. At the same time a systematic search is made through the entire alimentary tract for any other bands or adhesions which may be present. It is not uncommon to find a controlling appendix acting as a sling to the terminal inch or two of the ileum and thus controlling the ileal effluent.

I suppose every surgeon in reviewing his experience can recall cases in which the removal of an anchored appendix has turned a thin, anxious-looking, miserable, dyspeptic man or woman into a prosperous and happy being, radiating euphletic jollity. The recollection of these cases does something to offset the memory of perhaps as many cases in which the same operation entirely failed to relieve the symptoms which drove the patient to seek surgical aid, and in which the co-existence of a first and last kink would render the effects of such an operation almost nugatory.

Operation, Incision.—In the middle line, from umbilicus to pubes. The so-called cosmetic or para-rectus scar incision is unsatisfactory as it affords only partial access to the abdomen at large and there is a risk of damaging the nerve supply of the rectus muscle. Someone recently observed that the day had gone by when the surgeon conducted his examination with two fingers in the abdomen and his eyes fixed on the ceiling.

Instruments.—The special cleft palate needle holder designed by Sir Arbuthnot Lane, and the concave retractor which was invented by him for this operation are extremely useful in dealing with adhesions in a deep pelvis.

After a general survey of the bowel, the loop of pelvic colon is drawn up and any adhesions or bands divided, the resulting raw surface being carefully "peritonised" to prevent the subsequent formation of adhesions.

The last few inches of the ileum are then examined and any band divided or a "controlling appendix," if present, removed.

The splenic and hepatic flexures are next examined and if necessary freed; in short after a general survey of the bowel any morbid condition met with is rectified.

The division of bands in the right iliac fossa is not entirely free from risk: living pathogenic organisms having been demonstrated in these acquired bands, hence in cases where the division of a Lane's band is necessary it is advisable to leave a small drain in for 24 hours.

To use a cant phrase, the results of this operation must be seen to be believed, and to deal exhaustively with its benefits would be to transgress the space at my disposal.

Two conditions, however, are so strikingly ameliorated as a result that they deserve a moment's attention: I refer to epilepsy and

sexual incompetence. With regard to the first I cannot do better than refer my reader to the article by White Robertson in the *British Medical Journal* for the 27th December, 1924, on "Chronic Intestinal Stasis and Epilepsy." (3)

Sir Arbuthnot Lane has so frequently drawn attention to the restoration of sexual powers as a result of freeing the ileal effluent that the only comment necessary in this connection is to remark that the division of the first and last kink may be and is in many cases as effective as the more serious operative procedures formerly practised.

THE VALUE OF THE ALDEHYDE TEST IN THE DIAGNOSIS OF KALA-AZAR.

By Capt. P. GANGULI, B.A., D.T.M. (Bengal),
Teacher of Medicine, Dacca Medical School.
(Being a paper read at the Medical Research
Section of the Indian Science Congress,
January, 1925.)

SINCE the accidental discovery of jellification of syphilitic serum on the addition of formalin by Gates and Pappacosta, the "formol-gel" test has been tried in many other diseases. The most important practical result was Napier's discovery that a remarkable change occurs in the serum of kala-azar patients, if a drop of commercial formalin is added to it. The serum becomes opaque and jellified. According to Napier's classification a serum giving a + + + aldehyde reaction turns at once like the white of a boiled egg. It was found, however, that unless a patient gave a definite and clear history of illness for four or five months, this "aldehyde" test was either negative or doubtful.

Since the discovery of this test, various workers have challenged its value, the most remarkable contribution being that from Colonel Elwes and Drs. Menon and Ramakrishnan. They showed that in 4 out of 49 cases liver puncture did not show Leishman-Donovan bodies although the aldehyde test was + + +. Again, in no less than 13 cases of clinical kala-azar, Leishman-Donovan bodies were found by liver puncture, although the aldehyde test was negative. It is a pity, however, that they did not mention the probable duration of the disease, for Napier reported in 1923 that the duration of the disease was an important factor in interpreting the results of this test. In the first few months of the disease, Leishman-Donovan bodies may be found in enormous numbers from spleen or liver puncture, although the aldehyde test is negative.

During my investigation on this subject, I have found that in various diseases other than kala-

azar the blood serum may be changed in such a way that the aldehyde test is positive, but it was never + + + as in advanced cases of kala-azar, except in one solitary case of spleno-medullary leukaemia, reported by me in February 1924. In no other cases of this disease was the test positive. It is probable that this case was one of double infection, but the diagnosis could not be definitely made, as spleen puncture is contraindicated in this disease and the patient refused to stay in the hospital for a sufficiently long time for observation.

Nowadays with improved methods of diagnosis, patients are rarely seen with an aldehyde test + + +; hence it is increasingly important to know whether a + + or a + aldehyde reaction is absolutely diagnostic of kala-azar. During my investigations in 1924 I have found positive reactions in some other conditions.

It was positive in five patients with chronic skin diseases suffering from mixed staphylococcal and streptococcal dermatitis. It was negative in 8 cases of the same nature.

It was positive in 8 cases of convalescent pneumonia. The blood serum was examined within one to three days after crisis occurred. Two cases, however, showed negative results.

It was positive in three chronic malarial cases. The spleen puncture showed no Leishman-Donovan bodies and the patients were cured by cinchona febrifuge. On the other hand, 38 cases of chronic malaria showed negative results.

So it will be seen that the mere presence of + + or + aldehyde reaction is not absolutely diagnostic of kala-azar. It should be noted that the positive phase of Napier's aldehyde test and of Brahmachari's globulin test depends on the increase in the globulin of the serum in kala-azar patients. At the Science Congress held in Madras in 1921, I observed that the turbidity of Ray's hæmolytic test, so much eulogised by H. Wu of the Peking Union Medical College, was due to precipitation of the excess of globulin present in the serum of kala-azar patients, and not to the presence of resistant erythrocytes and shadow corpuscles as thought by Dr. Ray. In September 1923, I reported that the euglobulin factor was much more increased than the paraglobulin factor, as shown by ammonium sulphate tests; and that jellification was not always dependent on the amount of globulin, although usually the time of jellification was inversely proportional to the amount of globulin present. That this phase of jellification is not always associated with increase in the globulin content is proved in some chronic malaria cases, where although we get profuse precipitation on the addition of aldehydes, we get no jellification at all.

Further investigation on this matter showed that addition of distilled water to the serum precipitated the euglobulin, the colloids of which were charged with negative electricity, as proved by the method of capillary analysis by dipping a

piece of blotting paper into a mixture of distilled water and serum and noting that the fluid rises uniformly on the strip of paper. I repeated the experiments with one-third saturated solution of ammonium sulphate, half-saturated solution of magnesium sulphate and 14 per cent. solution of sodium sulphate; the results were the same in all the cases.

The next investigation was directed towards finding the electric charges of the paraglobulin colloids, which were obtained after dialysing the euglobulin and treating the filtrate with saturated solution of magnesium sulphate and dipping strips of filter paper into it. The rise of fluid in the paper was again uniform, showing that the colloids of paraglobulin are also charged with negative electricity.

It may be deduced from these experiments that addition of formalin introduces positive ions into the serum by dissociation of the electrolytes present in the serum. There must be some variation in the electrolytic conditions present in the serum which causes the formation of more suspensoids than emulsoids in the mixture in the majority of cases of chronic malaria. I have commenced investigations into the changes—if any—of the saline constituents of the serum which may have an influence on the osmotic pressure of the dispersion medium, so that precipitation occurs without jellification in the serum of some chronic malaria and other cases, when formalin is added to it.

The results of my investigation on the contents of the blood are tabulated as follows. Ray's method, with certain modifications, was adopted. The results are given in grammes of nitrogen per 100 c.c. of the serum:—

TABLE I.

Advanced Kala-azar cases of over five months' duration.

		Euglobulin.	Paraglobulin.
No. 1	..	0.304	0.4
No. 2	..	0.36	0.23
No. 3	..	0.52	0.36
No. 4	..	0.46	0.30
Average	..	0.411	0.32

TABLE II.

Normal healthy individuals.

		Euglobulin.	Paraglobulin.
No. 1	..	0.026	0.36
No. 2	..	0.032	0.42
No. 3	..	0.030	0.24
No. 4	..	0.036	0.22
Average	..	0.031	0.31

TABLE III.

Early cases of Kala-azar of less than four months' duration.

		Euglobulin.	Paraglobulin.
No. 1 (less than one month)	..	0.06	0.28
No. 2 (less than two months)	..	0.09	0.41
No. 3 (between 2 and 3 months)	..	0.13	0.32
No. 4 (between 3 and 4 months)	..	0.20	0.36

TABLE IV.

Chronic Malaria cases with a Positive Aldehyde Test.

		Euglobulin.	Paraglobulin.
No. 1	..	0.20	0.40
No. 2	..	0.168	0.32
Average	..	0.184	0.36

TABLE V.

Chronic Malaria cases with a Negative Aldehyde Test.

		Euglobulin.	Paraglobulin.
No. 1	..	0.12	0.20
No. 2	..	0.136	0.32
Average	..	0.128	0.26

It will be seen from these tables that in normal human beings the average nitrogen value of euglobulin in grammes per 100 c.c. of the serum is 0.031, whereas it is 0.411 in advanced kala-azar patients, i.e., more than 13 times that of the normal serum. In early cases of kala-azar, the nitrogen value of the euglobulin is gradually increased according to the duration of the disease. In 2 cases of chronic malaria, though the euglobulin factor was increased, yet its nitrogen value did not approach that in kala-azar of advanced type, even after two years of suffering. It will be seen that the increase of the euglobulin factor in kala-azar is a very gradual procedure and is associated directly with the duration of the disease.

It is known that antibodies reside in the euglobulin factor of the serum, and the suggestion that in kala-azar the gradual accumulation of antibodies leads to the increase in the euglobulin seems to be very plausible. Attempts have been made to prove the existence of complement-fixing antibodies and other antibodies in kala-azar sera, but no satisfactory conclusions have yet been arrived at. But it appears that in all cases—except in convalescent pneumonia—where the aldehyde test has been positive, the diseases are of a chronic nature and lead to a gradual accumulation of antibodies. Syphilis, chronic malaria and chronic skin diseases are instances of this kind, where the formation of antibodies is a slow procedure. In convalescent pneumonia the formation of antibodies is very rapid, as is shown by crisis within seven days. Again, even after kala-azar is practically cured, the elimination of antibodies takes some time, with the result that the aldehyde test remains still positive for one or two months after Leishman-Donovan bodies disappear from the spleen or liver. The disappearance of a positive reaction is again a gradual procedure and takes place as slowly or as quickly as was the case with its appearance. There is, however, one difference. In the beginning of the disease the jellification is more marked than the opacity, and it is only by passing through the mixture a beam of sunlight, which is known as the *Tyndall phenomenon*, that the precipitates are demonstrable in early cases; whereas the disappearance of the aldehyde reaction after cure is heralded by lengthening of the time and final disappearance of jellification, long before the excess of precipitation has vanished.

The value of the aldehyde test is thus a purely negative one. There was not a single case of

kala-azar with a clear history of more than five months' duration in which spleen puncture showed Leishman-Donovan bodies, where the aldehyde test was negative. Eight suspected cases with clinical symptoms of kala-azar and a kala-azar blood picture were thus investigated. The thirteen cases mentioned by Colonel Elwes were probably early cases of kala-azar, where, although Leishman-Donovan bodies were numerous in smears from liver punctures, the euglobulin factor was not sufficiently developed to give a positive aldehyde test. But in all cases of suspected kala-azar with a clear history of duration of five months or over, a negative reaction is definite evidence that they are not suffering from kala-azar.

OBSERVATIONS ON THE TREATMENT OF KALA-AZAR WITH UREA STIBAMINE IN THE MEDICAL OUT-PATIENT DEPARTMENT OF THE MEDICAL COLLEGE HOSPITAL, CALCUTTA.

By N. C. KAPUR, M.R.C.S. (Eng.), L.R.C.P. (Lond.),
MAJOR, I.M.S.,

Resident Physician, Medical College Hospital, Calcutta.

THE prolonged course of treatment required to bring about sterilization with tartar emetic or

sodium antimonyl tartrate in cases of kala-azar, and the fact that in a definite percentage of cases the disease is resistant to these salts led me to give a trial to urea stibamine, which had given such remarkably beneficial results in the hands of many previous workers. The cases treated were a series of unselected cases from the out-patient department of the Calcutta Medical College Hospital.

The present paper gives in tabular form the results of treatment with urea stibamine of the first fifty cases. Table A gives a series of cases treated with urea stibamine from the very beginning, and Table B consists of cases resistant to antimonyl tartrates and subsequently cured with urea stibamine.

The cultures of the venous blood were carried out in the kala-azar research laboratory, under the direct supervision of Dr. U. N. Brahmachari. The technique was carried out by his assistant, Dr. B. Maity, and he states that it consists in culturing citrated peripheral blood on N.N.N. medium at an average temperature of 25°C. The time of observation before treatment was begun was from 6 to 10 days, and after treatment from 2 to 3 weeks. It is the usual custom to send kala-azar patients from the out-patient department of the Medical College Hospitals' group to this laboratory for blood culture.

TABLE A.

Observations.—

(1) The course of treatment with urea stibamine for bringing about cure in kala-azar is remarkably short. In some of the cases cure took place in only seven days. In cases of the antimonyl tartrates the course of treatment frequently extends to more than three months.

(2) The average number of injections required for a course of treatment with urea stibamine is about seven to ten, whereas in the case of antimonyl tartrates it frequently amounts to thirty or more.

(3) The beneficial effects obtained with urea stibamine in cases resistant to the antimonyl tartrates are strikingly shewn in Table B.

(4) Jaundice and albuminuria were no contra-indications to the treatment of kala-azar with urea stibamine. Such cases are best treated with small doses, slowly increased.

(5) No signs of intolerance were observed in any of the cases. Sometimes a reactionary fever took place after injection which subsided after a few hours.

(6) Cases in which signs of intolerance showed themselves after injection of sodium antimonyl tartrate bore urea stibamine very well.

(7) The most striking results with urea stibamine are:—

(a) Rapid disappearance of the splenic enlargement;

(b) rapid subsidence of the fever;

(c) early disappearance of the leucopenia; and

(d) the short treatment required for a complete cure.

INTRAVENOUS ANÆSTHESIA IN SURGICAL PRACTICE.

By J. P. ARLAND,

LIEUT., I.M.S., (T.C.),

Indian Station Hospital, Kirkee.

I HAVE used intravenous anæsthesia in my practice with most gratifying results.

The following few cases are cited:—

Case No. 1.—No. 378092, Orderly Mangal Singh of the Overseas Depôt, Kirkee, was admitted to the Indian Station Hospital, Kirkee, on 8th April, 1924, suffering from a chronic sinus on the dorsum of the left forearm, two inches below the elbow, the result of an old badly set fracture.

Conservative measures were adopted with no result. The sinus was freely discharging and the pain was marked. The x-ray picture was very vague and gave no help. I saw the patient

on 9th July, 1924, and decided to enlarge the sinus and explore its depth. Intravenous anæsthesia was adopted.

Technique.—The skin over the median basilic vein was infiltrated with a few minims of a 0.5 per cent. solution of apothesine (Parké, Davis & Co.), and the vein exposed. An aneurism needle was passed under the vessel and a ligature was drawn in place. The arm was next elevated, while at the same time pressure was exerted over the brachial artery in order to prevent blood entering the part, and a tight bandage sufficient to obliterate the brachial pulse applied $2\frac{1}{2}$ in. above the elbow joint. The collapsed vein was lifted up by means of the ligature and 40 c.c. of a 0.5 per cent. solution of apothesine injected against the venous flow. The injection was made under pressure by means of an ordinary 10 c.c. glass syringe with a rubber connection to an ordinary infusion cannula. The cannula having been removed, the ligature was tightened and the wound closed. Anæsthesia was immediate and profound. The sinus was enlarged by an incision 2 in. long and a large sequestrum removed. The control was slowly relaxed and removed. The patient made an uneventful recovery.

Case No. 2.—No. 3556, Sepoy Fateh Mohd. Khan, 4th 2nd Bombay Pioneers, was admitted on 3rd July, 1924, for a chronic sinus on the volar surface of the lower half of the left forearm. He stated that he was injured by a sharp plank of wood which broke away inside his forearm on 2nd May, 1924.

Technique.—The technique adopted here was slightly different. The first bandage was applied 4 in. above the elbow joint and a second one 1 in. below. The median basilic vein was exposed and the injected solution confined to the area between the bandages. Anæsthesia was immediate in the area between the bandages and ten minutes elapsed before the part below the distal bandage was anæsthetic. An incision $1\frac{1}{2}$ in. was made, the muscles separated and an irregular piece of wood $3\frac{1}{2}$ in. by 3 in. was removed. The patient made a rapid recovery.

Case No. 3.—No. 9496, Sapper Gajab Bhanze, Royal Bombay Sappers and Miners, was admitted to the Indian Station Hospital, Kirkee, with multiple sores on his penis. Circumcision was decided upon.

Technique.—The skin at the root of the penis was infiltrated with 0.5 per cent. apothesine and the deep dorsal vein of the penis exposed. The vein was lifted by means of an aneurism needle and a ligature drawn into position. Twenty-five c.c. of a 0.5 per cent. solution of apothesine was injected and the ligature tightened. A soft flexible rubber catheter was tied round the root of the penis to prevent some of the anæsthetic solution escaping by the superficial dorsal vein and other small branches. Anæsthesia was instantaneous and profound. The patient was discharged cured.

Case No. 4.—My bearer, Velu, was stung by a scorpion on the pulp of the right thumb. The pain was very severe and according to him was ascending up the forearm. He was taken to the hospital and the median basilic exposed by infiltration with a 0.5 per cent. solution of apothesine.

The arm was elevated, pressure made on the brachial artery and a tight bandage applied 3 in. above the elbow to obliterate the arterial flow: 40 c.c. of a 0.5 per cent. solution of apothesine was introduced into the vein, which was then ligatured. The pain disappeared instantaneously. The bandage was kept in place for 30 minutes, after which it was slowly relaxed. Pain had completely vanished.

Case No. 5.—No. 3574, Lascar Gini Appala-swamy of the Indian Ordnance Department, was admitted to the Indian Station Hospital, Kirkee, on 19th September, 1924, suffering from gangrene of the right foot. It was decided to amputate the leg in the lower third.

Technique.—The great saphenous vein was exposed by infiltration with a 0.5 per cent. solution of apothesine behind the femoral condyle, and a ligature was drawn under it. The leg and thigh were elevated while the femoral pulse was obliterated by digital pressure. After a few minutes the limb was lowered and a broad bandage was applied 3 in. above the knee sufficiently tightly to prevent the blood entering the leg. The vein was drawn up by means of the ligature and 40 c.c. of a 0.5 per cent. solution of apothesine injected. Anæsthesia was immediate and the leg was amputated. The patient recovered.

Case No. 6.—No. 19455, Sapper Sakaram Savant, Royal Bombay Sappers and Miners, was admitted to the Indian Station Hospital, Kirkee, on 21st October, 1924, suffering from a large palmar abscess of the left hand.

Technique.—A small vein 1 in. above the wrist on the volar surface was exposed and a ligature drawn in place. The hand was elevated and a tight bandage applied 3 in. above the wrist. The vein exposed was injected with 25 c.c. of a 0.5 per cent. solution of apothesine. Anæsthesia was perfect and the abscess was opened. The patient recovered.

Practical Points.—

(1) The limb is rendered ischæmic, because the saline constituents of the blood interfere with the proper action of the anæsthetic.

(2) The control bandage must be sufficiently tight to obliterate the arterial and venous flow, thus preventing the blood from entering and the solution from leaving the part.

(3) It is important to inject the solution under pressure.

(4) The control bandage is to be slowly relaxed and removed.

(5) For major operations a preliminary injection of morphia and scopolamine is to be administered.

(6) The apothesine solution must be prepared with distilled water.

(7) Esmarck's rubber bandage, applied to the limb from below upwards, is an excellent means of rendering the part bloodless.

[Note.—Lieut. Arland's book on "Local Intravenous Anæsthesia in Surgical Practice" is about to be published by Messrs. Baillière, Tindall & Cox. Editor, I.M.G.]

QUININE PLUS ALKALIES IN THE TREATMENT OF MALARIA.

By K. V. RAJU,

M. & S. M. Railway Hospital, Hubli.

It was with great interest that I read Major Sinton's recent article in the *Indian Medical Gazette* on this line of treatment, as his reasons for such a line of treatment appeared to be very convincing, and accordingly, with the approval of my chief medical officer, I commenced a trial of the method on in-patients in hospital and on educated and intelligent out-patients.

As soon as a patient is admitted to this hospital for "fever," it is the routine practice to examine his blood microscopically. It is surprising how many patients who are clinically typical cases of malaria give negative findings in blood films. These patients get their regular paroxysms of fever, each typical of an attack of malaria, with all its stages, and yet examination of blood films often fails to shew the parasites. The reason probably is that when such a person falls ill, his first procedure is to take an aperient, and if this fails to reduce the fever, to take a dose of quinine. It is only when both measures fail that he calls in a doctor or comes to hospital, and he does not understand that, in taking a preliminary dose of quinine, he is rendering accurate diagnosis by the doctor doubly difficult.

I have accordingly divided the cases here reported on into two groups:—(a) Those in which malarial parasites were found in the blood films, i.e., proved malaria; and (b) those which were clinically typical of malaria, but in which examination of two or more blood films on different occasions failed to shew parasites.

The routine treatment of "fever" at this hospital is, first, to administer a saline aperient, and then await the onset of a rigor in order to take blood films for examination, if the patient has given a history of rigors.

The treatment was carried out in accordance with the instructions given by Major Sinton; using his alkaline mixture (for an adult: sodium bicarbonate 60 grs., sodium citrate 40 grs., and water to 1 oz.), and his quinine mixture (for an adult: quinine sulphate 10 grs., citric acid 30 grs., magnesium sulphate 60 grs., with water to 1 oz.). On

the first day 4 doses of the alkaline mixture, and 2 of the quinine mixture are given, the latter on each occasion 15 minutes after the alkaline mixture; for the next 4 days, 3 doses a day of the alkaline mixture, followed after a 15 minutes' interval by 3 doses of the quinine mixture; and for the next 2 days, 2 doses of alkaline mixture, followed after a 15 minutes' interval by 2 doses of the quinine mixture; the patient taking in all during the week 180 grains of quinine sulphate in solution. In every case the patient's blood has been examined before his discharge from hospital, and was invariably found to be negative.

Brief Notes on the Cases Treated.

(a) *Malaria proved microscopically*; 19 cases; 17 of them in-patients.

Case 1.—Afebrile after 40 grs. of quinine. Given 70 grs. in all. Discharged 9th day.

Case 2.—Afebrile after 20 grs. Discharged 8th day.

Case 3.—Afebrile after 20 grs. Discharged 8th day.

Case 4.—Afebrile after 50 grs. in two days; the fever had been quotidian. Discharged 8th day.

Case 5.—Afebrile after 20 grs. The fever had been quotidian; mixed benign and malignant tertian infection. Crescents still found in the blood after 100 grs. had been given. Discharged 12th day.

Case 6.—Afebrile after 20 grs. Mixed benign and malignant tertian infection. Discharged 8th day.

Case 7.—Afebrile after 40 grs. Benign tertian infection. Discharged 10th day.

Case 8.—Afebrile after 20 grs. Benign tertian infection. Discharged 8th day.

Case 9.—Afebrile after 20 grs. Discharged 7th day.

Case 10.—Afebrile after 20 grs. Discharged 9th day.

Case 11.—Benign tertian infection; still febrile after 40 grs.; then developed small-pox.

Case 12.—Afebrile after 20 grs.

Case 13.—Afebrile after 20 grs.

Case 14.—Still febrile after 50 grs.; patient refused to stay in hospital for further investigation.

Case 15.—Afebrile after 50 grs.

Case 16.—Out-patient. Benign tertian infection; afebrile after 50 grs. in two days.

Case 17.—Out-patient. Malignant tertian infection; afebrile after 50 grs. in two days. Subsequently relapsed; now under treatment again.

Case 18.—Mixed benign and malignant tertian infections; given 10 grs. of quinine hydrobromide intravenously in 20 c.c. of water; fever then stopped; discharged 8th day. Blood pressure at the time of the injection 95 mm.

Case 19.—Benign tertian infection; treated with acid quinine sulphate mixture; afebrile after 30 grs. Discharged 7th day.

(b) *Cases clinically malaria; but no parasites found in films*; 11 cases.

Case 1.—Afebrile after 60 grs.

Case 2.—Tinct. Cinchona Co., 5 drms. given; later 1 drm. quinine sulphate; still febrile with nausea and sickness. On 8th day given 10 grs. quinine hydrochloride intramuscularly; afebrile subsequently.

Case 3.—Afebrile after 20 grs. Discharged 7th day.

Case 4.—Afebrile after 20 grs.; spleen very much enlarged. Discharged 10th day.

Case 5.—Fever for three weeks with previous irregular quinine treatment; afebrile after 50 grs. Discharged 9th day.

Case 6.—Afebrile after 20 grs.

Case 7.—Two rigors in hospital before commencing treatment; afebrile after 20 grs.

Case 8.—Marked nausea on the quinine and alkaline treatment; given 10 grs. of quinine hydrochloride intramuscularly; fever stopped thereafter. Discharged 10th day.

Case 9.—Afebrile after 50 grs. in two days.

Case 10.—Quartan temperature chart; afebrile after 50 grs.

Case 11.—Afebrile after 50 grs.

CONCLUSIONS.

(1) As the doses of the two mixtures have to be given according to a strict time-table, the method is more suitable for in-patients than for out-patients.

(2) In the 17 cases of proved malaria in the first series treated with the quinine and alkaline treatment alone, the patients became afebrile after 20 grains of quinine in 9 cases; after 40 grains in 2 cases; and after 50 grains in 4 cases. Crescents were still found in a patient who had taken 100 grains.

(3) In the 9 cases of clinical malaria in the second series, treated with the quinine and alkaline treatment alone, the patients became afebrile after 20 grains of quinine in 4 instances; after 50 grains in 4 instances; and after 60 grains in 1 instance.

(4) In the majority of cases the mixtures are well tolerated, whilst there is the additional psychological effect of giving two mixtures instead of one to illiterate patients.

(5) Although all these patients were instructed to return to the hospital if fever recurred, the only one who did so was the patient who had received an intravenous injection,—Case 18 of the first series,—33 days after the injection. He was now placed on treatment with quinine and alkalies, and was discharged well on the 10th day.

(6) We are now trying the combined quinine and alkali treatment side by side with treatment with the ordinary acid quinine sulphate mixture as a control.

(7) The scantiness of parasite findings is a feature of the series. If there is any drug which could be administered to drive parasites into the peripheral circulation, it would be of benefit to know of it; arecaline hydrobromide is said to possess this property, but I have been unable to secure this drug from any chemist.

In conclusion I have to thank my officers, Dr. A. I. Jackson and Dr. C. A. Kirton for encouragement in this work and for assistance in the publication of these cases.

[Note.—According to James, ("Malaria at Home and Abroad"), if a single blood film from undoubted malarial cases be examined, parasites are only found in some 40 per cent. of cases; the use of the thick film as a supplementary measure—using the technique advocated by Knowles and Das Gupta, *Indian Medical Gazette*, September, 1924, much improves the percentage of positive findings.—EDITOR, J.M.G.]

CHOROIDAL HÆMORRHAGE FOLLOWING CATARACT EXTRACTION.

By M. M. CRUICKSHANK, B.Sc., M.B., Ch.B.,
CAPTAIN, I.M.S.

THESE notes on choroidal hæmorrhage are based on 30 cases occurring throughout a series of 2,777 cases of cataract extraction done by Dr. Holland of Quetta, and his staff, during two seasons at Shikarpur, Sind, where the incidence of glaucoma is very high.

Tonometry and Choroidal Hæmorrhage.—Perhaps the most striking fact noted with regard to the complications following cataract extraction, was the effect which the routine use of the tonometer had on the incidence of choroidal hæmorrhage. The tonometer used was MacLean's (1). In the treatment of glaucomatous cataract the importance and the necessity of estimating the tension with the tonometer was proved. At best the figures serve only as a rough guide, and in many instances give quite fallacious ideas as to the amount of intraocular tension. More especially is this so in the prominent type of eye, where a certain degree of elasticity gives a false sense of normal tension, the tonometer reading in these cases ranging from 45 mm. to 50 mm. Hg. Cases received in the operating theatre from the out-patient room without any note as to tension were found to give readings of 50 mm. Hg. and more. Cases with a warning note as to tension, sent in for extraction with capsulotomy or for preliminary iridectomy, were on several occasions found to register with the tonometer 100 mm. Hg. or more, and unless for the relief of pain, were refused operation. On the other hand cases sent in with a "cavé tension" were found to be normal and were operated upon in the usual way, the lens being expressed in the capsule, with good results.

What tonometer reading then should decide one in favour of either extraction with capsulotomy or preliminary iridectomy? Holland advises that extraction with capsulotomy should be done in all cases where the limits of normal tension are exceeded, that is where the tonometer registers more than 42 mm. Hg. Where the tension is over 50 mm. a preliminary iridectomy should be done, followed by extraction in the capsule three to twelve months later, the time interval depending on how far the preliminary iridectomy has checked the progress of the glaucoma, perception of light and the pupillary reaction being taken as the indications that the retina is in a condition to admit of hopes of vision. It is doubtful whether anything is to be gained by performing a capsulotomy in these cases.

What is the limit of intraocular tension beyond which a case should be regarded as inoperable? One must regard a tonometer reading of 70 mm. Hg. or over as dangerous, more especially if any degree of arterio-sclerosis with high blood pressure is present. To such a patient, having

perception of light and who is very anxious for operation, one must make it clear that there can be little hope for much improvement in vision and that a serious complication may follow the operation, namely choroidal hæmorrhage. Opinions vary widely on this point. Some would have it that tension has little to do with the onset of choroidal hæmorrhage, pointing to the fact that choroidal hæmorrhage occurs in eyes in which the tension is normal, though it is doubtful if it ever occurs in eyes which are healthy. Advocates of this view operate upon high tension eyes, removing the lens in the capsule with varying results. Others again advocate operation, but after some preliminary procedure has been carried out, such as preliminary iridectomy, or posterior sclerotomy, with removal of the lens later, in its capsule or by the capsulotomy method. Others again would unhesitatingly class such cases as inoperable. If one does operate upon cases in which the tension is high, then it is advisable to perform the operation very slowly. The incision is made slowly, the aqueous being allowed to escape slowly, so that the retinal and choroidal vessels may adapt themselves to the change in intraocular tension. The incision made, it is advisable to place a moist pad on the eye and wait ten or fifteen minutes before making the iridectomy and removing the lens. If Fisher's double hook is used throughout the operation, there will be less tendency for the lens to be shot out of the eye on the completion of the incision, an accident which very frequently occurs if a speculum be used. If the lens tends to extrude itself slowly, it should be allowed to do so unaided. If the lens does not present, then a capsulotomy should be done and the lens substance carefully and gently milked out, or if very gentle pressure with the hook over the lower corneal margin succeeds in starting the lens forward, then capsulotomy can be dispensed with. In a glaucomatous eye one does not wish to run the risk of any post-operative complication, such as iritis, which might be set up by cortical remains in the anterior chamber, and for this reason expression of the lens in the capsule is to be preferred.

Cases Selected to Demonstrate the Value of Tonometry.

1. Tension with fingers plus 1. Sent in for extraction with capsulotomy.
Pupil active. Tension—30 mm. Hg.
Expressed in the capsule.
Result: V = v.g.

I collected over a dozen such cases, which were sent in for preliminary iridectomy or for extraction with capsulotomy, in which the tension ranged from 22 mm. to 40 mm. Hg. In all of these the lens was removed in the capsule with good results.

2. Tension with fingers plus 1. Sent in for extraction with iridectomy.
Pupil somewhat sluggish. Tension = 50 mm. Hg.
After the iridectomy had been made, the lens slowly extruded itself unaided.
Result: not improved.

3. Tension with fingers plus 1. Sent in for extraction with capsulotomy.
Pupil active. Tension = 50 mm. Hg.
Extraction with capsulotomy.
Result: V = v.g.
In comparing cases Nos. 2 and 3 the question might be asked: "Does the extrusion of a lens unaided point to a degeneration of the zonular fibres occurring concurrently with degeneration of the retina?"
4. Tension with fingers plus 1. Sent in for extraction with iridectomy.
This case presented none of the classical signs of glaucoma.
Pupil active. Lens white. Tension = 70 mm. Hg.
Extraction with capsulotomy.
Result: choroidal hæmorrhage: evisceration later.
This was the only case in which choroidal hæmorrhage occurred after the routine use of the tonometer during the 1923 season.
5. Tension with fingers plus 2 (? more.) . Sent in for preliminary iridectomy.
Patient stated that he had perception of light. Pupils very sluggish to light. Lens of a sea green hue.
Projection bad. Tension = 98 mm. Hg.
Refused operation.
This is the highest tonometer reading which I have recorded in any case with perception of light.
6. No note with regard to tension. Sent in for expression in the capsule.
Tension = 85 mm. Hg.
In this case a posterior sclerotomy was done, and the lens removed in the capsule. No choroidal hæmorrhage resulted.
Visual result was hand movements at four feet, sufficient to allow patient to find his way about. Thirty such cases were collected, with tonometer readings varying from 55 mm. to 110 mm. Hg. The usual routine in such cases was, if there were perception of light, to perform a preliminary iridectomy. In no case with a reading of 100 mm. Hg. or over was there perception of light, and unless for the relief of pain, operation was refused.
7. Case of double glaucomatous cataract.
R. eye. Pupil active. Tension = 90 mm. Hg.
Vision = Perception of light.
L. eye. Pupil inactive. Tension = 70 mm. Hg.
Vision = Nil.
In the right eye the lens was extracted with capsulotomy, the incision being made slowly and an interval of fifteen minutes being allowed to elapse between the making of the iridectomy and the extraction of the lens.
Result: no choroidal hæmorrhage.
Vision = hand movements.
In the left eye a broad iridectomy was done for relief of pain.
Though, during 1923, only one case of choroidal hæmorrhage occurred after the routine use of the tonometer, yet, during 1924, three cases occurred in which the tonometer reading was within normal limits. Intraocular hæmorrhage may occur immediately after the operation, more usually, however, it occurs a few hours later. It may be slight and cease, the eye being preserved, but with loss of vision, or it may be expulsive, the vitreous welling out between the lips of the wound, accompanied by a stream of blood which flows freely over the face, and the grey membrane of the retina may sometimes be seen protruding between the edges of the section (2).

The only treatment is evisceration. Though usually occurring in high tension eyes, it may be brought on by the patient making some exertion, such as getting up, vomiting, straining at stool, etc. It may occur in any eye in which the vessels are sclerosed.

Reviewing the above selected cases it will be seen that tonometry, though a valuable guide, is not the only guide as to the operative measures to be followed in the treatment of glaucomatous cataract, and in the prevention of choroidal hæmorrhage. One must also take into consideration how long the tension has lasted, whether the onset of the tension was sudden or not, and whether or not the patient suffers from arterio-sclerosis with high blood pressure. The degree of tension will matter little if the choroidal vessels are healthy, while a slight increase in intraocular tension in a patient the subject of arterio-sclerosis, will call for great care and judgment. W. R. Parker(3), in a comparative study of results obtained in 1,421 operations, states, that while the three cases of expulsive hæmorrhage reported in his series occurred in patients with advanced arterio-sclerosis, yet "there was no indication that a hæmorrhage was more likely to occur than in any one of a large number of patients with equally severe symptoms on whom a similar operation was successfully performed."

Three cases of choroidal hæmorrhage occurred in my hands in which the tension was within normal limits. One in a man aged 35 years, and two in patients between 75 and 80 years of age. In all three cases the hæmorrhage was not expulsive and the form of the globe was preserved with a clear cornea. In all, pain was complained of before leaving the operating theatre. The onset of such sudden acute pain is pathognomonic of intraocular hæmorrhage. Each was given an injection of morphia gr. $\frac{1}{4}$, put to bed, and warned against drinking any fluid; this in case the fluid might cause the onset of vomiting, not an uncommon concomitant of choroidal hæmorrhage. The increasing intraocular pressure due to the hæmorrhage apparently constricts the choroidal vessels and arrests further bleeding, provided that the hæmorrhage has not been expulsive from the start. In such cases, however, the globe ultimately shrinks to a greater or less degree, depending on the amount of hæmorrhage. In a fourth case, in a man of 65 years, whose intraocular tension registered 50 mm. Hg., pain was complained of immediately after the incision had been completed. Nothing further was done, the eye bandaged, an injection of morphia gr. $\frac{1}{4}$ given, and the patient put to bed. A week later the lens was removed in the capsule by Smith's method, no iridectomy being done, and the eye bandaged for seven days. The patient made a normal recovery, with a circular, clear, black pupil, vision being simply perception of light. There was, however, no hæmorrhage, the complaint of pain after the incision being taken as a warning that the vessels were dilating and tend-

ing to rupture. The intraocular pressure was maintained by leaving the lens *in situ* and bandaging the eye, thus giving the vessels time to adapt their walls to the altered conditions of intraocular tension, the lens being removed seven days later without any untoward results. The tension of this patient's other eye was 32 mm. Hg. The lens in this instance was removed by the Barraquer method, no iridectomy being done, a circular black pupil remaining, the vision being very good. E. E. Maddox(4) reports a case in which he successfully extracted a cataract in the capsule, the patient having lost the other eye as a result of choroidal hæmorrhage. His method consisted in performing a preliminary iridectomy at least one week before the extraction. The patient was suitably prepared, being given calcium lactate the night before and morphia and bromide on the morning of operation. Before commencing the operation, venesection was done and the episcleral veins of the eye pricked. A corneal suture was employed and a gentle pressure bandage applied. After operation hot turpentine stipes were applied to the abdomen and the feet kept warm, to promote circulation of blood in the abdomen and lower extremities.

Hari Shankar of Muttra(5) states that if a small pledget of moist wool is placed on the exposed eye-ball, and gentle pressure exerted backwards on the globe, for about one minute or, as he puts it, "whilst you mentally count two hundred" then "the danger of expulsive hæmorrhage is diminished when the tension is plus and the *vis a tergo* of the vitreous is absent or is reduced considerably."

The Drawn-up or Boat-shaped Pupil.—The drawn-up pupil, which is so frequently seen both after expression of the cataractous lens in its capsule, and after extraction with capsulotomy, cannot be dismissed as the result of a hasty or careless toilet of the wound, though these may play some part in its causation. Even when a complete iridectomy has been made and the pillars of the coloboma carefully replaced, this combination may be seen. It may result from the patient squeezing his lids under the bandage, forcing the aqueous out of the anterior chamber, and thus rolling the edges of the coloboma into the lips of the wound, where they become incarcerated, with the result that the pupil is drawn up. It may be a result of vitreous loss(6). This drawn-up pupil may not interfere with vision in any way, but the cosmetic effect is bad.

Occasionally vision is interfered with, when a second operation has to be undertaken in order to lower the pupil. This little operative measure, Beer's iridectomy, is well worth doing when any interference with vision is present. A thin, preferably worn, von Graefe knife, with a narrow blade, should be used. A transverse incision, about 4 mm. in length, is made in the lower half of the cornea at that point where the lower margin of the new pupil will lie. The blade is

entered flat as in making an incision for an iridectomy. When the counterpuncture has been made, the edge of the blade is turned through a right-angle and brought out perpendicular to the corneal surface. Two points are to be noted in making the incision. First, it ought to be made low down on the corneal surface. The tendency is to make it too high up, with the result that the new pupil is not quite central. One must err then in making the lower margin of the new pupil low rather than high. Second, to ensure that the resulting corneal scar will be so thin as to be almost invisible, the knife must be brought out at right-angles to the corneal surface. To make the new pupil one merely picks up the edge of the drawn-up pupil with a curved iris forceps, and withdrawing it gently from the wound, makes a narrow iridectomy. Col. H. Kirkpatrick(2) states that "the pupil of an eye from which vitreous escape has occurred during a cataract operation has a characteristic appearance, unless the vitreous escape has been reduced and the iris replaced. This is due to the folding back of the iris which occurs. The lower margin describes a wide curve, and the iris is seen to be shaped like a crescent, the inverted pillars of the coloboma, if an iridectomy has been made, forming the horns."

Factors which tend to cause iris prolapse undoubtedly play a large part in the formation of the drawn-up or boat-shaped pupil. Similarly, attention to these details which make for the elimination of iris prolapse will prove of equal value in preventing the drawing up of the pupil after extraction of the lens. As with prolapse of the iris, so with the boat-shaped pupil, both can be eliminated, save for indiscretion on the part of the patient, by removing the lens according to Barraquer's technique. The factors enumerated above as possible causes of the boat-shaped pupil do not, however, entirely solve the problem, and the reason why a drawn-up pupil should go on becoming more and more drawn-up weeks after the wound has healed, till little or no pupil is left, still requires elucidation. This occurred in one case in which I expressed the lens in the capsule by Smith's method. The patient, a Mohammedan, aged about 55 to 60 years, had a slightly drawn-up pupil after operation, but vision was good, and he was discharged and told to return in two months for glasses. In a month's time he came back with a request for glasses. I then noticed that the pupil was very markedly drawn up, but not sufficient to interfere with vision. He was told that he could not have glasses for another four weeks, and he returned to his work in the bazaar. I then lost sight of him for about two months, when he again appeared, this time complaining that he could not see. Examination showed the iris drawn completely upwards across the anterior chamber, leaving a pupil not much larger than a good sized pin's head near the centre of the upper

sclero-corneal margin. He agreed to further operative treatment, and an iridotomy was done, through an incision in the lower third of the cornea, it being impossible to reach with iris forceps the small portion of iris margin remaining free. The result was an irregularly circular, central pupil, roughly 3 mm. in diameter, which, much to his relief, restored to him his vision.

Delirium after Cataract Operation.—W. A. Fisher(7) emphasises the importance of getting a history from old people before operating. If possible a friend should remain with them in hospital, and on the slightest tendency to delirium, they should be awakened. He relates an interesting case of a man who had violent delirium. After being awakened he slept soundly and naturally, and in the morning related a terrifying dream, which he had had during the night, just before the nurse wakened him. Two cases of loss of mental control occurred during the 1924 season. One in an old woman after the intracapsular operation, and the other in an intelligent, though rather neurasthenic Anglo-Indian, aged 52, whose lens had been removed by the Barraquer method. In the first case morphia was tried, but proved useless, the patient becoming normal in her behaviour when the sound eye was released. In the second case, the patient, who apparently was making every endeavour to keep himself under control throughout the operation, broke down the moment both eyes were bandaged, becoming wildly excited, shouting that he was going mad, and making efforts to remove the bandage. The sound eye was released, and the patient regained his mental control, though during the night, despite morphia and chloral hydrate, his wife, who remained with him, reported that he had carried on like a lunatic, having to be coaxed to stay in his bed.

Mercurial Clouding of the Cornea.—This complication, which may or may not interfere with vision, is occasionally seen when the conjunctival sac has been washed out with strong solutions of perchloride of mercury. It is a complication which need never occur, and is avoided by simply washing any excess of perchloride of mercury out of the conjunctival sac with a little sterile water or with saline before the operation is begun. The cloudiness is diffuse and in well marked cases presents a tessellated appearance over the posterior corneal surface. According to Leber, when for any reason the endothelium of Descemet's membrane is destroyed, the aqueous humour infiltrates the corneal substance, which consequently becomes oedematous and cloudy(8). Presumably the strong mercurial solution, passing into the anterior chamber, alters the endothelium on the posterior surface of the cornea. The protective layer being removed, infiltration of the cornea by the aqueous takes place. The condition is unaccompanied by any signs of inflammation, and if slight, clears up without treatment. If severe, a certain amount of opacity will remain, which will interfere with vision, and for which

treatment is useless, though diosmine might be tried.

Striate Keratitis.—Fuchs(8) uses the more correct name of traumatic striate opacity of the cornea. A keratitis implies, at least, an inflammation of the cornea, in which Bowman's tubes, running at right-angles across successive corneal lamellæ, are distended with exudate, the condition seen in a parenchymatous keratitis. In traumatic striate opacity of the cornea there are no signs of inflammation, and there is no interference in any way with the healing of the wound. Some believe that the condition is due to a wrinkling of Descemet's membrane due to the difference in tension in the vertical and horizontal diameters of the cornea, the result of the incision near the corneal margin; others, that it is due to injury to Descemet's membrane during delivery of the lens, more especially when a large hard lens has been forced through a small incision with resulting aqueous infiltration of the corneal substance. T. Harrison Butler(9) using the corneal microscope and Gullstrand's slit lamp, clears away any doubts as to what the condition present on the posterior surface of the cornea actually is. He states:—"In most deep corneal inflammations Descemet's membrane is thrown into folds, and occasionally Bowman's membrane is folded. Such folds are almost constant after any operation upon the cornea, but exactly similar ones are seen in keratitis." This minor complication, which is apparent at the first dressing, is of no significance, requires no treatment, and clears up in a few days.

A Mirror of Hospital Practice.

AN OBSCURE CASE OF PNEUMOCOCCAL INFECTION.

By A. K. NANDI,

CAPTAIN, I.M.S.,

Senior Medical Officer, East Persian Line, Nushki, Baluchistan.

No. 4850, Sepoy H. K., 4/10th B. Regiment, aged 22 years, was admitted to the Military

Hospital at D. on the 12th February, 1924, complaining of having suffered from fever and an acute pain in the præcordial area of the left side of the chest for the past three days. Cough and expectoration were absent.

On admission his temperature was 100.4° ; pulse 100, very soft and almost thready; respiration rate 36. On examination, the *alæ nasi* did not shew any noticeable movement; the tongue was coated and constipation present; nothing abnormal could be detected on examination of the chest, except that the heart sounds were weak and had a muffled character. There was no clinical evidence of pneumonia.

The constipation having been relieved by calomel and sodium sulphate, the temperature dropped to normal the next morning, but thereafter a continued remittant pyrexia set in, only dropping to normal on the 12th day after admission. The temperature chart was as shewn on p. 218.

Daily examination of the chest failed to reveal anything characteristic. The temperature oscillated between 99 and 102°F. ; the pulse between 80 and 100; the respiration rate between 27 and 40. The patient had lost all appetite, and could only be induced with difficulty to take a few ozs. of essence of meat and two ozs. of brandy, well diluted, daily. He complained continuously of the severe pain in the præcordial area.

On the 16th February, for the first time, examination raised the suspicion of a very faint and very occasional pleuritic rub in the left axillary region. A sinapism was applied and gave partial relief; whilst the constipation had to be continuously treated by saline aperients.

On the 21st February, the patient complained of pain in his feet, both of which were now found to be swollen, owing to bilateral thrombosis. This condition took about two weeks to clear up.

On the 23rd February, the eleventh day after admission, a definite but only occasional pleuritic rub could be detected in the left axilla, whilst the respiratory murmur, vocal resonance and vocal fremitus were diminished over the same area. A slight but insignificant cough now set in, the patient coughing only some four or five times a day, with a scanty, clear and colourless expectoration. This shewed alveolar epithelium, and pneumococci on microscopical examination, but no tubercle bacilli. The case, therefore, appeared to be one of pneumococcal pneumonia, without clinical signs of this disease.

In addition to the usual expectorant mixture, he was given an alkaline potassium iodide mixture orally, and an inhalation containing creasote, turpentine and carbolic acid. The appetite still continued to be very poor. On the 24th February, the temperature came down to 98°F. for the first time since the 13th February, but later in the day he coughed up about a fluid drachm of bright red fresh blood. The sputum was again most carefully examined, but no tubercle bacilli could be found. Hæmoptysis continued for

three days, some three to five times a day, but repeated examination of the sputum failed to reveal tubercle bacilli. He did not cough more than eight times a day at this period. The temperature chart had now become intermittent in character; pain in the chest was still severe; there was some improvement in the condition of the feet; but the cardiac sounds were very weak, and the patient's condition critical. On the 5th March he had a sudden attack of agonising pain in the left side of the chest, and I found him doubled up with pain, drenched in a cold perspiration, and with the pulse extremely thready and scarcely perceptible. Morphia and atropine were at once given hypodermically, and, despite the cardiac condition, were repeated each night in order to secure sleep.

On the 12th March he was evacuated to the

tional in central pneumonia. The profound depressant action of the toxin on the heart was marked from the outset. The sudden onset of pleural effusion with only the very slightest previous indications of pleurisy is a noteworthy feature of the case. The hæmoptysis from the 13th to the 16th day after admission suggested tuberculosis, but repeated examination of the sputum failed to shew tubercle bacilli, and up to the date of writing—28th March—no evidence of tuberculosis has been discovered. Finally, the characters of the pleural exudate were peculiar; a hæmorrhage exudate in place of the usual sero-fibrinous or purulent one.

The onset of a fluid hæmoptysis late in the course of a pneumonia is usually ascribed to streptococcal infection. Post, writing on "focal infection," in Nelson's "Loose Leaf Living

CLINICAL CHART.

Corps... 4/10th BL.

(To be attached to the case sheet.)

No. 4850.

Rank and Name *Sefroy*

HK. Age 22 Service 1 year.

Disease *Pneumococcal Pneumonia
terminating in Empyema.*

Date of Admission 12-2-24. Discharge..... Result Transferred to S.S.H. Quetta on 12-3-24

central military hospital of the district. The temperature chart was now of a definitely hectic type, but the cardiac condition was slowly improving. Definite signs of fluid in the left pleural cavity could now be detected, and a provisional diagnosis of empyema was made. The resources of the local hospital, unfortunately, did not permit one to make a total leucocyte count, and this valuable aid to diagnosis was not available. On the 15th March, aspiration of the left pleural cavity withdrew about 32 ozs. of a sero-sanguineous fluid, in which pneumococci were found.

Summary.—The case appears to have been one which commenced as a central pneumonia, of which severe pain in the præcordial region was the only symptom, and without any clinical evidence of the disease. Pain, however, is excep-

Medicine," has suggested the possibility of mutation between these two organisms in closed cavities.

The case is at least one with peculiar characters, and of aberrant type.

AN UNUSUAL COMPLICATION OF TYPHOID FEVER.

By A. T. ROY, L.M.S.,

Hazaribagh.

A YOUNG unmarried Hindu girl, aged 12, had a typical attack of typhoid fever of mild type. At the end of the third week, when the temperature was gradually coming down in typical

step-ladder fashion, spasmodic movements of the muscles of the head and face set in, of sudden onset and sudden disappearance. These spasmodic movements gradually spread over the whole body and extremities, occurring several times during the day and also during sleep at nights. They were always bilateral.

Major Lee, the Civil Surgeon, on consultation, thought that the movements were choreiform in type. Unlike true chorea, however, if the muscles were forcibly held, e.g., those of the extremities, the spasmodic movements at once ceased, only to recur when pressure was discontinued. The spasms would continue for 15 to 30 minutes, but were unattended by any pain, although they left the patient exhausted.

There was extreme constipation at the time, and the urine was very scanty, although the bladder was full. The temperature subsided by the end of the fourth week, but the choreiform movements continued after the fever had subsided. It is to be noted that the father of the child gave a history of rheumatism; she herself was fairly well nourished, and had never previously had such attacks. The menstrual flow had not yet appeared.

Treatment. The constipation and the distended bladder were relieved by mechanical means; and calcium lactate, 15 grs. with parathyroid extract, gr. 1, was given thrice daily. Lemon whey and fresh fruit juices were given. In the course of a couple of weeks the symptoms subsided, and the child is now in good health.

Remarks. Chorea is known to follow acute infections and intoxications, and is, of course, well known as a complication of rheumatic fever in childhood. The writer, however, has never seen it as a complication of typhoid fever. The severe constipation and scanty urine were marked features of the case, and may have contributed to the onset of the chorea. The choreiform movements having suggested a deficiency in calcium, calcium was administered both orally as calcium lactate, and also in the diet prescribed; parathyroid extract being added in order to assist the calcium metabolism. Vines has shewn that calcium salts are present in the blood in two forms: combined with the plasma, where they take part in blood coagulation; and free, in an ionised form. Biochemists have also shewn that excess of calcium depresses, whilst deficit of calcium increases nervous irritability, magnesium taking the place of the calcium in the latter condition. Harrower has shewn that the activity of the parathyroids governs the calcium metabolism of the body. Hence, in the present case, the indications appeared to be to give calcium salts both orally and in the diet, and to add parathyroid extract.

AN UNUSUAL EFFECT OF MALARIA UPON THE HEART.

By KRISHAN LAL KHERA, M.B., B.S.,

Jaranwala, Lyallpur, Punjab.

S. M., a Hindu male aged 35, consulted me on the 19th December, 1924, complaining of fever coming on daily at 4 p.m. with rigor and passing off at 11 p.m., and of one week's duration. On examination I found the radial pulse on both sides practically imperceptible, with only an occasional beat perceptible. The spleen and liver were both enlarged. On auscultation, the heart was beating exactly as does the foetal heart, with no regular pauses between the sounds, which were weak and scarcely distinguishable from one another. On percussion there was no abnormality in the outline of the heart. With all this, the patient was walking about, complaining of no cardiac symptoms except slight palpitation on walking. The heart was beating at the rate of 210 per minute, and the temperature at the time of examination (9 a.m.) was 98° F.

I put the patient on to quinine, 10 grs. t.d.s. in solution, and on the following morning found that the radial pulse had returned, but was very weak, and at a rate of 90 per minute. He had not had the usual rigor on the preceding day.

On continuing the quinine treatment his pulse rate came down to 82 on the 21st, and the heart sounds were regular and clear, and there was no fever. On the 22nd the pulse rate was 74, with normal heart sounds.

The case illustrates the profound influence of malaria on the cardiac mechanism.

A CASE OF TRIPLETS.

By BINODE KRISHNA BANERJI, M.B.,

*Coomar Charitable Dispensary, Chauditala P. O.,
Hughli.*

I was called in to see a multipara, aged about 22, in her fourth confinement, with a history of previous miscarriage due to cholera. She had lost her husband a month previously, and had had to travel in a railway carriage with slight pains just before the date due for delivery. On my arrival the family doctor informed me that she had had a fit a few hours previously and had been given gr. $\frac{1}{2}$ of morphia hypodermically. The *dai* in charge stated that the os was dilated to one finger width. The patient was exhausted and restless.

On abdominal palpation, a case of twins was diagnosed, and on vaginal examination the os was found to be dilated, with the presenting head low down. Forceps delivery was resorted to, but the child was born in blue asphyxia, probably due to pressure on the cord by the head of the second child. The cord was at

once cut between two artery forceps, and artificial respiration resorted to.

After a second examination, a second child was delivered by forceps; and later a third child "in caul" on pressure on the fundus. A hot douche was given, and an injection of ergotine citrate, and a post-partum mixture prescribed. The placenta was a large one; all three children were of the same sex (female) and equally developed. They all lived for only some 48 hours; the mother, however, made an uneventful recovery.

THE DOSAGE OF ANTI-TETANIC SERUM.

By M. A. KRISHNA IYER, L.M.P.,
Natcharkoil, Tanjore District.

In the October 1924 issue of the *Indian Medical Gazette*, Dr. Nagendra Nath Ghosh reported the treatment of a case of puerperal tetanus with anti-tetanic serum in doses much smaller than those generally recommended or advocated in the text books. Shortly after the publication of his case, I had occasion to deal with two cases of tetanus, one after the other, for which I adopted the same procedure of treating them with small doses of anti-tetanic serum with success. Though there is nothing unusual in these cases, it may be of interest to note that smaller doses of serum than the single massive doses of 15,000 to 20,000 units usually advocated can often be employed with success, and with considerable saving of expenditure.

Case 1. On the 9th October, 1924, I was called to see a woman, aged 30, in a neighbouring village, on the eighth day of her illness. The infection with tetanus had apparently been contracted by the genital route as the result of a miscarriage in the fourth month of pregnancy, some 25 days previously. When I saw her, lock-jaw was complete, and the spasms of the whole body so numerous that I witnessed about 50 attacks during the hour which I spent in attendance on her that day. The temperature was 101.5° F., and risus sardonicus was well marked.

Two hypodermic injections of the serum, each of 1,500 units were given that day; and repeated doses each of 1,500 units on the 10th, 11th and 12th October. The number of convulsions was now reduced, but her condition was otherwise unchanged. The same dose of 1,500 units was again repeated on the 14th, 16th, 17th, 18th and 19th October, the doses being given intravenously.

On the 19th, her condition was markedly improved; two further similar intravenous injections were given on the 21st and 23rd, after which the spasms ceased to appear; she could sit up and take food, and even walk with assistance.

From the beginning the usual bromide and chloral mixture was given. The injections were now stopped, and convalescence was uneventful.

Case 2. This was in a boy aged 9 years whom I first saw on the third day of illness. He had been vaccinated some three weeks previously, and, as I could find no other lesion which could have been responsible for the tetanus, I am inclined to incriminate the vaccination. The symptoms and signs were typical of tetanus, and although the number of spasms was less frequent than in the first case, the opisthotonus posture assumed during each spasm was very marked and continued for some twenty minutes at a time, the boy screaming out during each attack.

I first saw him on the 2nd January, 1925, when the tetanus was of three days' duration, and gave 750 units hypodermically that day. From the 3rd to the 9th January, a daily dose of 750 units was given intravenously. By this time the boy's condition was much improved; he could open his mouth; the spasms were few and of short duration; he could sit up and slept well. Two more intravenous injections, each of 750 units, were given on the 11th and 13th. By the 15th the patient could walk with help, and could take his normal food. In this case also the usual bromide and chloral mixture was given.

As pointed out by Dr. N. N. Ghosh, repeated administration of small doses of anti-tetanic serum may be just as efficacious as the administration of one or two heroic doses. There were no untoward symptoms of any kind in these two cases as the result of giving small doses in place of large; whilst the cost of anti-tetanic serum is so high that large single doses prove very expensive. The serum used in these two cases was that of Messrs. Parke, Davis & Co.

A TUMOUR OF THE ABDOMINAL WALL.

By R. K. BASU,
Assistant Surgeon, Balasore.

M. B., a Mahomedan male, aged about 32 was admitted to the Balasore Hospital on the 27th August, 1924.

Clinical signs on admission.—On inspection, a distinct swelling is visible in the middle of abdomen, more in the lower part than in the upper; on palpation, the swelling is distinctly hard to the touch; its area is 6 in. \times 6 in; the skin is movable over it and it is also distinctly tender; no redness of the skin nor any cedema in it. The feeling of the swelling is like that of a solid abdominal tumour; its duration is a fortnight before admission and it is in the same condition as at first; there is no fluctuation in the swelling.

General condition of the patient.—He has no fever; the eyes are sunken; he lies with the thigh flexed; the tongue a bit coated; not much constipated.

Treatment.—The usual applications of glycerine belladonna, iodine, ung. hydrarg co. and plumbi acetat were applied to the skin over the swelling and well bandaged; by the mouth liq. hydrarg. perchlor. $m. xx$; tinct. hyoscyamus $m. xx$ in an ounce of water was given thrice daily. On 28th August, 1924, a subcutaneous injection of the following vaccine was given:—*B. coli communis*—100 million, *B. coli communior*—100 million, *B. acid lactici*—20 millions, totalling 1 c.c. of fluid. In the afternoon of the day of injection he had a slight rise of temperature and had the usual uneasiness of fever. On 29th August, 1924, there was a distinct change in the site and position of the tumour-like mass, it extended from the right iliac region to the middle of navel and was hard as before. For his constipation pulv. glycyrrhizæ co. one drm. was given and a soap water enema—2 pints. A bromide mixture, one dose, was given at night to ease his pain. The next day, 30th August, 1924, he was put on to potass. iodide and hexamine by the mouth. On 1st September, 1924, it was found that the tumour-like mass was reduced to half its former size and the patient's general condition had improved. He was all along kept on sago and barley water; no milk was given. On 4th September, 1924, only a mass 2 in. \times 2 in. was palpable and the abdomen was soft and painless.

On 7th September, 1924, hardly any mass was felt and the man could walk about easily and there were no signs of the swelling; he was discharged cured.

Peculiar points in this case are—the hard tumour-like mass in the middle of abdomen round the navel and its change of size within 2 days of regular treatment; that the *Bacillus coli* vaccine injection appeared to have much to do with the subsiding of that mass; that the inflammatory mass was absorbed without any suppuration, and there was hardly any fever, though the inflammation persisted for such a long time and extended over a fair area of the abdominal wall.

A NOTE ON THE INTRAVENOUS USE OF UROTROPINE.

By Capt. N. N. GHOSH, M.B.,

Civil Assistant Surgeon, Siliguri.

I HAVE used urotropine intravenously for the past two years in a mofussil dispensary, where treatment generally depends upon clinical diagnosis, and where the success or failure of a drug in a particular case is judged by clinical results only. One of the most common

diseases treated in all dispensaries in India is scabies, milder cases of which are cured very rapidly by sulphur ointment, if it be properly applied. But cases of scabies are not infrequently encountered complicated with suppurative lesions almost all over the body, with inflammatory swelling of the extremities and dependent parts, and which take very long to cure with sulphur ointment only.

In such cases I have tried urotropine intravenously with very good results, using a 10 per cent. solution in normal saline, and a dosage of 10 c.c. of this solution daily for three or four consecutive days. During the period of injections, the septic lesions were washed with hot water only. It was found that after three or four such injections, the lesions cleared up wonderfully, and when sulphur ointment was now applied healing was rapid. If the course of injections was not followed up by application of sulphur ointment, the lesions would become pustular again. The sulphur ointment is necessary to kill the burrowing parasite, but the urotropine injections appear to eliminate the secondary sepsis due to scratching.

In these days of injection therapy it is not difficult to get patients to permit intravenous injections, even for such a condition as severe scabies. I have also used urotropine intravenously with apparent good results in suppression of the urine due to cholera, in acute cystitis, and in inflammatory stricture of the urethra.

A CASE OF TETANUS.

By BINODE KRISHNA BANERJEE, M.B.,

Coomar Charitable Dispensary, Chanditala P. O.,
Hughli.

THE patient, a child of $4\frac{1}{2}$ years of age, was sent into hospital in the early morning with information that his tongue had been firmly clenched between his teeth since 10 p.m. the previous night. The father being a *gwalla* (milkman), had secured the services of an *ojha* (devil-exorcist) during the night. On his arrival at hospital I found the child to be suffering from tetanus fits in rapid succession, with a dirty looking ulcer on the brow, some 10 days old, and due to a fall as the source of the mischief. The tongue was black in colour and adematous. It was released under chloroform anaesthesia with the greatest difficulty, and hardly a drop of fluid could be made to pass by the mouth.

The ulcer was cleaned up and antitetanic serum given; six injections in all,—the first two intravenously. The fits subsided after the second injection, but rectal feeding had to be continued till the 5th day, after which milk

could be taken between the teeth. A bromide and chloral mixture was also given, and the child made a complete recovery. In all 9,000 units of serum were given, the patient's father not being able to afford more. The patient's recovery, even although such an advanced case, is of interest.

A CASE OF TICK TYPHUS.

By Dr. C. E. S. NORMAN, F.R.F.P. & S., D.P.H., L.A.H.,
Chief Medical Officer, S. I. Railway, Trichinopoly;
and

C. S. RAMACHANDRAN, M.B., B.S.,
Assistant Surgeon.

WE have read with much interest the articles about tick typhus in the *Indian Medical Gazette*. The following notes deal with a case which is similar to those described. The patient was a retired Indian Army Colonel, aged 60, who arrived in Trichinopoly from Bangalore on 16th December, 1924, where he had been staying 3 months. He was not in contact with any ticks at Bangalore. In the bungalow occupied by him at Trichinopoly he noticed ticks, and said it was quite possible for him to have been bitten by a tick while asleep any time between the 16th December and the 2nd of January, on which date the fever began. The onset was sudden with slight shivering not amounting to ague, and lasting for about 10 minutes, severe headache, pains in all his bones and joints, and pains in his eyes, which became very congested. Severe pains in his abdomen on 3rd January, 1925. These abdominal pains wore off in about 3 to 4 days. Vomited coffee-coloured material on 4th January, 1925. When I saw him on 7th January, 1925, he appeared to have slight jaundice which disappeared in a few days.

The fever was continuous; it lasted 19 days and ended by lysis. The rash appeared on the 3rd day. It was first noticed on the thighs and legs, a few hours later on the abdomen and chest, and then arms. Spots were noticed on his face on the 7th day but were most marked on the 12th to the 14th day. His eye symptoms were most marked on the 12th to the 14th day.

At the onset the rash consisted of discrete purplish-pink spots, fading on pressure. At the height of the disease the rash was distributed on the face, body, thighs, legs, arms, palms of the hands and soles of the feet. Generally speaking the eruption was discrete, but owing to the large number of spots many became confluent, especially on the forearms near the wrists, and near the knees. A few spots on the abdomen became confluent. The spots faded on pressure at first, but later showed a tendency not to completely disappear; this was most marked on the legs and feet, when most of the spots towards the end

of the fever did not disappear on pressure. Some of the older spots seemed to have a tiny depression in the centre. The spots were purplish-pink in colour; this colour changed to a more reddish colour later on and on the legs and feet were pronouncedly dark-red in colour, almost like limited hæmorrhages under the skin, towards the end of his fever. The spots became fainter in colour and smaller in size, but 6 days after his temperature became normal were quite noticeable, least so on his face. He was discharged from hospital on 25th January, 1925. A fortnight after discharge, spots could still be seen on his thighs and legs and some on his abdomen. He went home, and I got a letter dated 16th February, 1925, saying that spots could still be seen.

The senior author first saw this patient on the 6th day. He had marked conjunctival injection and pains in the eyes. The injection and the pains were very bad from the 12th to the 14th day, at the time the rash on his face became most marked. His right eye was exceptionally tender and there was a slight increase in tension. He could not bear any light from the 12th till the 14th day. His eye symptoms rapidly cleared with the abatement of his disease. On the 6th day the liver and spleen were both slightly enlarged and painful; they became normal in size by the 9th day and the pain disappeared. Marked congestion of the throat, hoarse voice, and gums covered with aphthous patches were present. Foul tongue; sleeplessness for first few nights, but the patient appeared drowsy. No albumin in the urine. As far as could be seen lice were excluded. Serum reactions were tested at the King Institute, Guindy. On the 15th day of disease his blood was sent for examination and the following was the result:—

Typhoid and all the	negative.
paratyphoid group.	negative.
Wassermann	.. strongly positive.
Weil Felix	.. inconclusive as not enough blood was sent, so a further sample was sent on the 22nd day of his disease and there was a negative result.

Examination of slides for malaria proved negative. Five slides were sent to the School of Tropical Medicine, Calcutta, for differential count, etc., but the results of examination were not forwarded. There were no evidence as to other cases in the locality.

CORRIGENDUM.

On p. 161 of our issue for last month, April 1925, in Dr. S. K. G. Dastidar's article on "Trichomonas Infection in the Urine," please substitute in the last paragraph, "may cause a mild urethritis, *unattended* with smarting and burning," for "may cause a mild urethritis, *attended* with smarting and burning."—
EDITOR, I. M. G.

Indian Medical Gazette.

MAY.

THE SUPPLY OF RURAL PHYSICIANS.

IN India the problem of village medical relief is ever before us; it is interesting to find that a very similar difficulty is being experienced in the United States where the wealth of the country might have been expected to render the supply of efficient medical aid an easy matter.

The subject has been investigated by officers of the General Education Board of the United States and all aspects of the question have been closely studied. The upshot of their enquires is that the provision of medical aid is a question of supply and demand. One remedy that has been suggested in America is also advocated in this country; it is to lessen the difficulty and expense of the medical curriculum and to flood the market, so that medical men will be compelled to seek a living in the country. The officers of the medical board have pronounced against this remedy; they hold that the greater attractions of large cities from the financial, social and professional points of view will appeal with equal force to practitioners of every type, and that a lowering of standards will not be effective.

In one respect Indian practice is superior to American; we have considered the possibility of subsidising the country practitioner for the benefit of the community and of lessening the drawbacks from which he suffers in the only way that is likely to be effective, viz., by making his financial prospects better than those of the average medical man in the large cities. The subject is one which ought to be carefully investigated in India; it would be interesting to find whether the graduates of the medical schools go to the country villages in larger proportion than the university graduates; if so an increase in the number of the medical schools will facilitate the solution of our

problem. But we must stipulate that while the education of the medical man may be made more practical and more specially directed towards the work which he is called on to perform, there must be no question of relaxing standards. If medical science is to justify its existence, there can be no question of turning out large numbers of quacks who are recognised as qualified practitioners. The unrecognised quack is harmless in comparison with the man who is sailing under false colours and who does nothing but bring discredit on medical science.

We still more strongly oppose the suggestion that the indigenous systems should be called in to supplement the supply of country practitioners. We have no quarrel with the worthy men who are earning their livelihood by the practice of the indigenous systems, but we must obstinately refuse to take them under our wing. We have quite enough lame ducklings of our own, without assuming responsibility for the still lamer ones belonging to other families. Our business is to set our own house in order and to improve the training of our qualified practitioners, not merely by giving them thoroughly practical courses of pre-graduate and pre-diploma training but also by giving them periodical courses of post-graduate training.

It is not by diminishing the efficiency of our medical men that progress will be secured, but by pushing forward with the work of making them better and more efficient doctors.

THE PREVENTIVE USE OF QUININE.

DR. HAROLD SEIDELIN in the October 1924 number of the *Transactions of the Royal Society of Tropical Medicine and Hygiene* writes on this most important subject. He refers to the tendency among medical men to regard the prophylactic use of quinine as a discredited measure, and he admits that the daily use of small doses of quinine, which is based on the theory that the sporozoites can be destroyed by small quantities of quinine, has not been established as a scientific procedure. He holds that the use of doses of fifteen grains on two days in each week has been proved to

be eminently successful in controlling malaria and he believes that the action of the drug is to kill the parasites at an early stage in their development before they have attained to sufficient numbers to cause clinical manifestations. He has found that the method is not enough to prevent infection and that many of the persons who take the preventive quinine show a few parasites in their blood, but in no case has the disease assumed a severe or resistant form.

It is important that such experiences should be recorded, as the tendency is to abandon one of the means of controlling malaria which has been firmly believed in for many years.

It is likely that some confusion has arisen owing to the known difficulty in sterilising persons who have acquired chronic infections because of delayed and insufficient treatment. It is easy to understand that a number of persons with such chronic infections may be very different material from a similar number of people who have just become infected. In the case of recently infected people short courses of quinine, such as ten days of fifteen or twenty grains daily, will quite probably result in a large proportion of cures, whereas in the case of the old infections such courses would cure only a trifling proportion of the patients. Perhaps too, it may be desirable to give up the use of the term quinine prophylaxis, as it has come to be associated with the fallacy that the sporozoites can be destroyed by much smaller doses of the drug than are needed to destroy the developed parasites. What should be aimed at is really an early treatment of the infection, and the only point at issue is whether it is better to carry out this early treatment on a mass scale, so that in highly malarious places each person would be given a short course of treatment of an effective nature at such a time that the parasites could not possibly have multiplied sufficiently to cause serious damage, and equally important that they should be attacked at a time when they are still confined to the blood stream or to parts of the body which are within reach of the quinine tide which results from the taking of effective doses; or whether it is better to wait until symptoms have appeared

and then carry out a thorough course of quinine treatment. In this connection it would appear that the earlier the treatment is commenced after infection the easier it is to sterilise the patient, and it may turn out that, while a ten days' course is found to be necessary after symptoms have actually appeared, the shorter two days' course may be sufficient within four or five days of the introduction of infection into the body. We grant that there is no complete scientific proof of the view that the parasites can so readily be eliminated immediately after their introduction into the body, but at any rate there is a good deal of evidence that benign tertian infections which have recently been produced for the treatment of general paralysis of the insane are surprisingly easy to cure by short courses of quinine, whereas we have plenty of evidence that chronic infections are most difficult to cure, even by prolonged courses. We have the further evidence that so simple a procedure as the taking of fifteen grains of quinine daily on two consecutive days in each week is sufficient to prevent any serious clinical manifestations of the disease, although frequent infection has been shown to occur, as was shown by the finding of parasites in the blood towards the end of the week and just before the weekly course of treatment was due.

In the cases in which parasites were found, by Dr. Seidelin, a course of ten days' treatment was usually prescribed, but in others it was deliberately omitted without harmful results.

Dr. Seidelin admits that it may be argued that the week-end system is not really a prophylactic but is an "abortive treatment."

It does not matter in the least whether this term or the term "early treatment" be adopted; the result is the control of the disease. The conditions under which such measures are desirable are probably not very common. Mosquito prophylaxis is undoubtedly much superior to quinine control, but in many cases it cannot be carried out effectively. Also the system is not desirable in places where the risk of infection is small, in such cases early treatment after symptoms have developed will probably be more suitable; but in cases in which mosquito control cannot be carried out

and in which the risk of infection is great, the week-end system of malaria control may yet prove to be a very valuable means of keeping malaria from damaging the individual and causing havoc among labour forces.

But the system must be carried out thoroughly or it will be ineffective and will bring quinine into disrepute. We must repeat that it is not enough to write out orders that quinine should be given in certain doses, the mixture must be made up under responsible control and the doses must be swallowed in the presence of some one who is interested in the results of the treatment.

It is hoped that steps will be taken to test the efficacy of quinine in treatments of varying duration in cases in which infection has been produced a few days previously, and in which parasites have just begun to appear in the peripheral blood. It may turn out that these are controllable by much briefer courses of quinine than the older infections. It is also possible that the chronic and resistant infections can be more suitably dealt with by intermittent courses of treatment such as three or four days' treatment in each week than by prolonged spells of quininisation.

SPECIAL ARTICLE.

DISORDERS OF MENSTRUATION.

(In the absence of gross abnormalities such as displacements, neoplasms, inflammations, etc.).

A CLINICAL LECTURE TO POST-GRADUATES.

By V. B. GREEN-ARMYTAGE, M.D., M.R.C.P.,

MAJOR, I.M.S.,

Second Professor of Obstetrics and Gynaecology,
Eden Hospital, Calcutta.

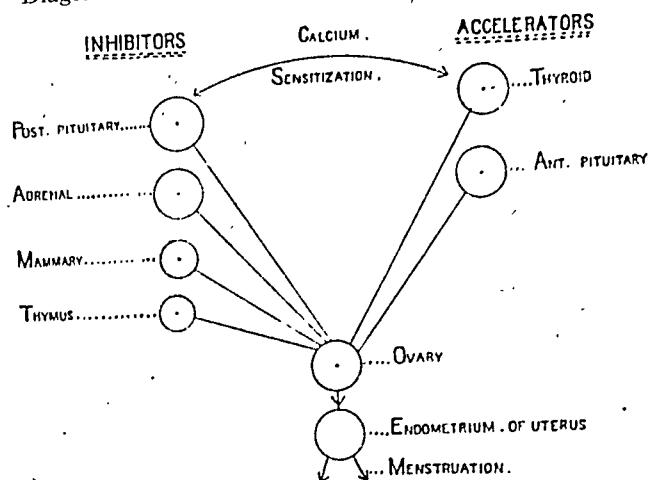

GENTLEMEN,

I have chosen the above title for the subject of our lecture to-day, because of its importance and difficulties in general practice; but, before I begin to speak to you about these cases which I have collected, I wish to make quite clear to you the facts on which our knowledge and treatment are based.

Menstruation may be looked upon as the uterus weeping over the loss of an ovum, and it depends upon an ovarian hormone which is sensitized by calcium. This hormone co-operates with other hormones from the endocrine glands; and it will perhaps make it clearer for you to understand this, if you will imagine that there is a form of executive board in the human female body for its common welfare. Some members of the board are

inhibitors, whilst others are accelerators of menstruation, and both these parties have calcium as their bond of union.

Diagrammatically I can represent it as follows:—

You may ask what proof I have of this. My answer is determined by clinical findings. For instance:—

1. (a) If the thyroid is overworking (as in exophthalmic goitre) we get *menorrhagia*.
(b) If it is deficient (as in myxædema, delayed puberty, or cretinism) we get *amenorrhæa*.
2. (a) If the anterior pituitary gland secretion is in excess, we get *acromegaly* and precocious genital development.
(b) If it is deficient, we get *amenorrhæa* and non-development of the genitals, and such conditions as an infantile or cochleate uterus.
3. (a) If the suprarenal gland secretion is in excess we get *amenorrhæa* with atrophy of the ovaries.
(b) If it is deficient we get the precocious menstruation of children with hypertrophy of the genital organs.
4. When the thymus gland atrophies, menstruation and ovarian function begin.

If the thymus persists, puberty is delayed.

5. The endometrium controls the excretion of calcium. The proof of this fact is that menstrual blood contains far more calcium than pre-menstrual circulating blood.

If you realise these well-known clinical facts, it is not difficult for you to understand the usual sequence of events which leads up to the monthly discharge from the uterus; for there would seem to be no doubt that what happens is that the calcium content of the blood gradually rises to a certain height. This calcium sensitizes especially the thyroid and anterior pituitary glands, which send a hormone to the endometrium, which in turn fires the trigger of menstruation. When the thyroid, endometrium, and ovaries have expended their energy, the inhibitors function and the process of building up for the next menstrual period begins.

There are three common types of menstrual disorder:

- (1) The *amenorrhæa* of puberty and adolescence;
- (2) the *menorrhagia* of (a) puberty, (b) the reproductive period, (c) the menopause; (3) *dysmenorrhæa*.

- (1) *The amenorrhæa of puberty and adolescence.*

The *amenorrhæa* of puberty and adolescence, which is not associated with gross symptoms of anæmia, has three common causes.

- (a) The calcium index is below normal, and consequently there is inadequate sensitization of the endocrines.

- (b) Under-development of those generative organs which especially depend upon the proper function of the thyroid and pituitary glands.

- (c) Lack of endocrine balance,—by this I mean that, either the inhibitors are over-active, or the accelerators are not mature,—the latter being by far the most common.

Treatment consists in raising the calcium index of the patient (1) by diet. Namely, ordering at least 2 pints of milk a day, Sanatogen, eggs, green vegetables (such as cabbage, spinnach, tomatoes, *brinjals*, ladies' fingers, young bamboo shoots), fish roe, underdone meat, home-made butter or *ghee*; liver, kidney, and sweetbread.

(2) By drugs, such as (a) Calcium carbonate, $\frac{1}{2}$ to 1 teaspoonful doses three times a day; (b) Calcium chloride, gr. 1 in 100 minims of sterile water, to be injected intramuscularly twice a week; (c) Parathyroid extract gr. 1/40th, Calcium lactate grs. 5, three times a day (P. D. & Co.).

(3) By prescribing endocrines which stimulate functional equilibrium, e.g., such a prescription as the following:—

Thyroid ext.	gr. $\frac{1}{2}$
Whole Pituitary ext.	gr. $1\frac{1}{2}$
Whole Ovarian ext.	grs. 3
Acid Carbollic	gr. $\frac{1}{4}$
M. Ft. Pil.			

One three times a day for not less than 6 to 12 weeks. If there is anemia, acid arseniosum gr. 1/60th is added.

(4) General hygienic treatment, such as looking after the bowels, and seeing that fresh air and exercises are taken.

Such treatment as outlined above is equally of value in those cases so frequently encountered before, or after marriage or childbirth.

(2) Menorrhagia.

(a) *The menorrhagia of puberty.*—My private records and experience in Bengal during the last fifteen years very clearly demonstrate that there are two common types of menorrhagia of puberty.

The first is when the periods last too long (i.e., from 10 to 12 days) but are not particularly profuse. This is the type most frequently seen in Bengali girls, and is as a rule due to imperfect development of the uterine musculature and lack of harmony among the executive board of endocrine glands.

The *treatment* of this type is to (1) avoid constipation and diminish the pelvic congestion by mild saline purgatives.

(2) A prescription, such as the Mist Ferri et Mag. Sulph. of all hospital pharmacopœias is useful, and a pill containing:—

Thyroid ext.	gr. $\frac{1}{2}$
Whole Pituitary ext.	gr. $1\frac{1}{2}$
Acid Arseniosum	gr. 1/60th

is most efficacious given three times a day for 6 to 12 weeks.

This type of case is rarely benefited by calcium, ergot or curetting.

The *second* type of case, where perhaps the periods are excessive and tend to recur too often, is most frequently seen in Anglo-Indian and European girls. The cause here is due, as a rule, to congestion and over-activity of the ovaries and thyroid. Moreover, the whole modern attitude towards sex matters and housing has to be considered as provocative.

In this type of case you will find that the best treatment is to encourage an open air life with plenty of exercise, early to bed and early to rise, and the avoidance of cinemas and erotic literature.

As regards drugs, a mixture containing iron, bromides, and magnesium sulphate is excellent, together with a pill made up of:—

Ergotine	grs. 3
Whole Pituitary ext.	gr. $1\frac{1}{2}$
Ext. Hydrastis. Canadensis	gr. $\frac{1}{2}$
Acid Carbollic	gr. $\frac{1}{4}$

One pill three times a day for 8 days before each period, and for the first 2 days of the period.

Calcium, which is so beloved by the general practitioner, is, I am sure, of no use whatever unless it is given in the form of calcium chloride gr. 1 dissolved in 100 minims of sterile water and injected intramuscularly thrice weekly; and seeing that this type of menorrhagia is due to increased calcium sensitization it is obvious that calcium is contra-indicated as a general rule.

Personally, I am a great believer in Swedish drill for these girls, and if they do not quickly react to the above treatment it is best to send them to the hills for a period of not less than three months.

Operations, such as curetting, are very rarely called for, that is if you realise the real cause of the hemorrhage; for in this type of case such an operation is only of temporary utility; in 280 such cases I have curetted only 11.

Occasionally masturbation is the root of the trouble, and therefore it may be necessary to make careful enquiries.

I see from my notes that in two cases (aged 14 and 16) I had to advise radium application to the endometrium, for in both girls medical and surgical measures had failed entirely. The pathological report after curetting was hypertrophic endometritis in both cases.

(b) *The menorrhagia of the reproductive period.*—All of you realise the extreme frequency of this condition. The causes are many and intimate, and every case will need careful investigation. The commonest causes are:—

1. Ovarian hyperactivity.
2. Coitus interruptus.
3. Prolonged engagements.
4. Contraceptive pessaries.
5. Hyperthyroidism, particularly after childbirth.

The less common causes are erotic literature, cinemas, dancing, climate, and masturbation.

The *treatment* of these cases is:—

Primarily to enquire into, and, if possible, remove the cause.

Secondly, a prescription such as:—

Mag. Sulph.	grs. 60
Potassium Bromide	grs. 20
Ferri Sulph.	grs. 5
Aqua Menth. Pip.	ad. 1 oz.

to be given three times a day, combined with the pill previously mentioned of ergot and post-pituitrin for eight days before each period and for the first two days of the period. A cold water enema, combined with very hot vaginal douches during the period, is also useful. If feasible, a change to the hills may be recommended.

If the above measures fail, however, curetting is the only treatment for the thickened and congested endometrium; and here I would again remind you that the cases of which I am speaking are those in which there is no displacement, neoplasm or inflammatory affection of the uterus and its appendages. If curetting fails, then you will have to resort to radium or vaginal hysterectomy.

(c) *The menorrhagia of the menopause.*—You all know how common this is among women over the age of 35, and also how important it is to make a complete examination of the patient in order to eliminate the chances of malignancy or tumour, but, apart from these entities, chronic metritis is extremely frequent, and from a clinical point of view there are two common types of patient; and I am showing you here twenty uteri removed by me by vaginal hysterectomy during the last ten months for this condition.

In one type the uterus is thick, hard and bulky, and in the other type it is thin and small. In both there may be erosions or tears associated with childbirth or abortions and old infections. These patients, you will find, have nearly always been curetted once or twice, and have submitted to practically every means of medical treatment without avail.

Both types of uterus are frequently met with, and as a result chronic metritis has been well named the "clinically malignant uterus," in order to distinguish it from the pathologically malignant uterus.

The treatment of these cases is, to all intents and purposes, hysterectomy; for if the Wassermann reaction is negative, and they fail to react to any medical or minor surgical procedure, such as curetting, they frequently bleed to death, or become so anæmic as to succumb to some secondary infection.

Vaginal hysterectomy is a peculiarly suitable operation for chronic metritis, and for this condition alone I have done sixty such operations during the last five years, with the loss of only one patient.

My own experience of radium for chronic metritis has been disappointing, for an acute inflammatory reaction is not at all uncommon and this leaves the patient in a worse condition than before.

(3) Dysmenorrhœa.

Painful menstruation is to-day divided into (1) that form which has some extrinsic cause, such as tumour, displacement, or inflammatory condition of the generative apparatus; and (2) that which is of the intrinsic type, where pelvic examination shows very little deviation from the normal, and consequently you are apt to assume that everything, anatomically and physiologically, is as it should be.

There are four common types of dysmenorrhœa frequently met with, i.e.:—

1. Dysmenorrhœa of puberty and adolescence.
2. Dysmenorrhœa of the early reproductive period of married life.
3. Dysmenorrhœa of the late reproductive period of married life.
4. Dysmenorrhœa of the menopause.

1. *Dysmenorrhœa of puberty and adolescence* is frequently found in anæmic school girls, typists, shop girls, factory hands, etc., and is the cause of much anxiety and loss of working hours.

Some of these cases are associated with a lack of calcium and thyroid and pituitary secretions, or a lack of harmony between the inhibitors and accelerators. Others are due to under-development of the uterus and cervix, which maintains the anteфлекed or retrofleked cochleate condition of pre-puberty days with its snout-shaped, pin-hole, or button cervix. Others again are merely secondary to occupational duties which result in poor abdominal musculature, constipation, and congestion of the ovaries.

The treatment of these cases is:—

(1) Hygienic, i.e., to promote an open air life, Swedish exercises and open bowels; and during, or just before the period, hot foot or hot sitz-baths.

(2) Increase the iron and calcium index by diet or drugs as suggested under the heading *amenorrhœa of puberty*.

(3) Prescribe a pill made up of:—

Thyroid ext.	gr. 1
Whole Pituitary ext.	grs. 2
Whole Ovarian ext.	grs. 3
Acid Arseniosum	gr. 1/60th

One pill twice a day which should be taken for a period of not less than 6 to 12 weeks.

For the actual pain there are a hundred drugs which are frequently prescribed,—an excellent indication of their uselessness. Personally, I order one of three, e.g., either antipyrin grs. 15, four hourly for four doses; or liq. sedans drs. 2 before and during the period; or luminal gr. 1 three times a day.

If all these methods fail after a prolonged trial, operation, dilatation, and curetting may be advised, but it is well to remember that unless the dilatation is done properly (to at least Hagar 9/12) it is rarely of use. Moreover, it is a useful clinical fact to remember that if there is any difficulty in slowly dilating up to this

size, the patient will probably be cured, but if the dilatation is easy, your operation will not relieve her.

You must remember that the so-called 'pin-hole' os does not of itself cause dysmenorrhœa, for the under-developed snout-shaped cervix and cochleate uterus with which it is associated is the real cause. Nor must you forget that the severe dysmenorrhœa of puberty and early married life is often associated with maldevelopment of the uterus and is one of the causes of sterility.

Stem pessaries are not to be recommended.

Very occasionally, in very severe cases, I have done what is spoken of as an anterior hysterotomy.

2. *Dysmenorrhœa of the early reproductive period of married life.*—This condition is most often associated with a very congested and thickened endometrium due to excessive coitus, or sub-involution of the uterus following childbirth, or some low-grade inflammatory infection of the uterus.

The treatment consists in very hot rectal and vaginal douching twice a day, and, if this fails, dilatation and curetting will probably be necessary, followed by iodised-phenol swabbing of the interior of the uterus.

Remember, if there is an inflammatory infection of the tubes and ovaries, under no circumstances should curetting be done, for, if you do so, an exacerbation of acute salpingitis is probable.

Careful enquiry as to a previous history of acute abdominal pain, fever, discharge, or possible dysuria, will give you the necessary clue, and a careful vaginal or rectal examination should elucidate the position of the uterus, and whether it is tender and fixed, or whether the tubes and ovaries are enlarged and matted together.

3. *Dysmenorrhœa of the late reproductive period of married life.*—This is frequently due to a fibroid or polypus of the uterus, or to a thickened endometrium or salpingitis, or may possibly be the commencement of one of those peculiar tumours which we speak of as a recto-vaginal adenomyoma.

Such cases should be referred to a specialist for opinion.

4. *Dysmenorrhœa of the menopause.*—This may be due to chronic metritis, or to a fibroid polypus, and sometimes is associated with commencing carcinoma of the body of the uterus.

Any case of this type of dysmenorrhœa should at once be referred to a specialist.

Current Topics.

The Microscopic Diagnosis of the Dysenteries at their onset.

By Dr. FRANK G. HAUGHWOUT.

Jl. American Med. Assoc., October 11th, 1924, p. 1156.

DR. HAUGHWOUT claims that in Manila he is able not only to make a correct diagnosis of the condition within two or three hours of the onset, but that the administration of serum is attended by exceedingly satisfactory clinical results. This is accomplished by the microscopic inspection of the cellular exudate, which affords criteria that enable a quick and reliable diagnosis of bacillary dysentery to be made, and sharply differentiates it from the protozoal dysenteries.

Until recently, the American literature has laid the greater stress on the relatively rare amoebic dysentery, until it has almost submerged the greater problem, bacillary dysentery.

Three essentials are involved in the successful management of a case of dysentery:—

1. Its differentiation from acute diarrhœa or other gastro-intestinal disorders of non-specific origin.

2. The early and accurate determination of the type of dysentery—whether bacillary or protozoal.

3. Prompt, adequate and sustained treatment with the appropriate remedy as indicated by the laboratory findings, together with the treatment of accompanying complications. This should be succeeded by a period of microscopic supervision during the post-dysentery stage, and until such time as microscopic evidence of ulcerative process is no longer obtainable. This applies to bacillary as well as protozoal dysentery.

A fatal outcome in dysentery, usually is due to one or more of the following causes:—

1. Delay on the part of the patient in seeking medical advice.

2. Failure to make a correct differential diagnosis, and, in consequence, treatment by the wrong method.

3. Failure promptly to administer treatment in adequate dosage.

4. Failure to treat complicating symptoms, such as dehydration in severe bacillary dysentery.

5. Inability to cope with early developing and overwhelming toxemia as seen in fulminating bacillary dysentery.

6. Neglect of secondary infections supervening on a primary bacillary or protozoal dysentery. This last contingency is by no means rare, and is responsible for the loss of many patients and the prolonged invalidism of others, who have weathered the storm of their dysentery.

Differentiation.—Bacillary dysenteries caused by the Flexner strains of *Bacillus dysenteriae* frequently give rise to constitutional symptoms so mild that clinical differentiation of them from those of amoebic dysentery is a practical impossibility. The rise of temperature is evanescent and may not exceed 1 degree Fahrenheit. Prostration is not marked and there are no recognizable symptoms of toxemia. In short, the general clinical picture is essentially similar to that of amoebic dysentery.

In these days, when the microscopic diagnosis of dysentery can be made so rapidly and so accurately, there is no longer any reason why the final diagnosis should not be made in the proper place—the laboratory, and at the proper time—immediately after the onset of the disturbance.

Dr. Haughwout is able to confirm the findings of Willmore and Bahr and Anderson and others, and has been able to supplement them with observations of his own on bacillary and amoebic dysentery as well as on balantidial dysentery, post-dysenteric colitis and various types of non-specific colitis and other pathological conditions in the colon.

The underlying principle of the method rests in the recognition of the two types of dysentery through the medium afforded by the cellular exudate that is produced as an expression of the pathological conditions of the two processes. Bacillary dysentery is an acute, toxic, inflammatory involvement of the colonic mucosa caused by *Bacillus dysenteriae*. In consequence it gives rise to a rich, purulent exudate, consisting mainly of polymorphonuclear leucocytes (about 90 per cent.) and phagocytic endothelial macrophages. Other cells are present in small numbers. A large proportion of all these cells bear the marks of toxic necrosis, and stigmas that are characteristic of bacillary dysentery and no other intestinal disorder. On the other hand, amoebic dysentery produces an exudate that bears a definite relation to the amount of secondary bacterial infection present, but which is always so scanty in volume and so lacking in the characteristics of bacillary exudates that no confusion can possibly arise.

Diagnosis.—The diagnosis of bacillary dysentery rests on the finding of an exudate exhibiting the characters already mentioned; that of amoebic dysentery rests on the discovery of active tissue-dwelling forms of *Entamoeba histolytica* containing ingested red blood corpuscles in surroundings that make it clear that *E. histolytica*, and no other agent, is responsible for the dysenteric symptoms. Bacillary dysentery super-

imposed on an amoebic dysentery produces an exudate of its own that is so massive and striking that it completely submerges the unobtrusive amoebic exudate, which is quite proper since, under these conditions, treatment is first directed toward the bacillary involvement, the less urgent amoebic process being dealt with later.

In the exudate of a case of bacillary dysentery the general background of the field is made up of polymorphonuclear leucocytes (neutrophils) in a marked state of toxic degeneration. Cellular damage, it will be noted, is quite uniform, nuclei and cytoplasm being equally involved. The nuclei of the leucocytes will be seen to have undergone the rather familiar annular degeneration, which, however, appears often to be especially marked in bacillary dysentery, although it is, of course, not a distinguishing characteristic of that condition. Other types of cells, as well as erythrocytes, will be seen to be distributed about the field. Prominent among the cells are numerous oval to elongated, and sometimes lobed cells, about twice the size of the polymorphonuclear leucocytes. Rounded to irregularly shaped dark staining masses lie in the cytoplasm of these cells. The darker of these bodies probably represent the remnants of cell nuclei that have been broken down in the process of toxic necrosis; the more lightly stained bodies that appear to lie in clear, vacuole-like spaces are erythrocytes that have been phagocytosed by the endothelial cells. Smaller, mono-nucleated cells of the plasma cell type, as well as extremely degenerated cells of uncertain origin, almost denuded of cytoplasm and nuclei, are in the field. The latter express the extreme effects of the toxic process produced by *Bacillus dysenteriae*, and are known as "ghost-cells." When bacillary dysentery exists, the polymorphonuclear leucocyte—endothelial macrophage—ghost-cell combination always can be assembled on microscopic study of the exudate; and the microscopist is completely justified in rendering a diagnosis of bacillary dysentery to the clinician. The author has never yet seen *Bacillus dysenteriae* recovered from a purulent bowel exudate that did not contain endothelial macrophages. Therefore, they always must be sought for, because occasionally one encounters cases in which a heavy purulent exudate is produced in connection with the activities of some bacterial organism other than *B. dysenteriae*.

A totally different picture will be found in the mucosanguinolent exudate passed by a patient who is suffering from an acute attack of amoebic dysentery.

The central figure in this picture is, of course, the trophozoite of *Entamoeba histolytica*. It will be seen to contain a number of partially digested erythrocytes. Charcot-Leyden crystals may be seen. Virtually all the other bodies in view are erythrocytes, which are to be recognized as the darker, homogenous, circular to elongated bodies. Other cells will easily be recognized by their nuclei, but few of them will be seen.

So far as we have evidence, no toxin is produced by the protozoon, and it is incapable of producing an inflammatory reaction *per se* in the tissues.

The consequence is that no particular type of cell is called forth from the wall of the intestine, and such cells as find their way from a small amoebic ulcer and into the mucoid discharge are very apt to show evidence of the action of the digestive ferments at their periphery, and under the microscope look very much as if pieces had been bitten off them. The nucleus is the last portion of the cells to be affected, and, as a result, the exudate of amoebic dysentery contains many of these partially destroyed cells—some of them consisting of little more than the nucleus, with a small remnant of the cytoplasm still adhering to it. These are called "pyknotic bodies." They are characteristic of protozoal dysentery, balantidial as well as amoebic. However, no diagnosis of amoebic dysentery should be made except on the finding of motile, tissue-dwelling forms of *Entamoeba histolytica*. The identification of this species in the presence of acute amoebic dysentery is not at all a difficult matter if one is working with fresh material.

The amoebæ are exceedingly active, showing lively movements of progression. If such amoebæ are found that contain erythrocytes in an active state of circulation in the endoplasm, they may for all practical purposes be designated *E. histolytica*, and the microscopist may rest serenely confident that he has made no mistake.

Endothelial macrophages need never be confounded with amoebæ. To begin with, they occur in a heavy leucocytic exudate such as one never sees in amoebic dysentery; moreover, they are not motile, and the erythrocytes which many of them contain do not circulate about in the containing cell, but instead lie passively in vacuole-like spaces that are sharply marked off from the remainder of the endoplasm.

In amoebic dysentery complicated by heavy secondary bacterial infection of the amoebic ulcers, the leucocytic exudate cannot be mistaken for that of bacillary dysentery.

A few trophozoites of *Entamoeba histolytica* containing ingested erythrocytes may be seen, the stool contains bacteria in enormous numbers. The deeply staining round to elongated bodies are erythrocytes. Scattered over the field are a number of polymorphonuclear leucocytes. It will be noted that in the main these are intact. That is to say, they show no evidence of the toxic degeneration that characterises the leucocytes of bacillary dysentery; likewise, very few of them show the evidence of proteolytic digestion characteristic of protozoal dysentery. In other words, most of them are leucocytes derived from bacterially infected amoebic ulcers. Endothelial macrophages and "ghost-cells" are totally lacking in the microscopic picture. In short, even in the face of the numerous leucocytes, brief inspection of this exudate will serve to distinguish it, beyond all doubt, from the exudate of bacillary dysentery.

In his summary, Dr. Haughwout states that the exudate of bacillary dysentery becomes organized within an hour or two of the onset of the first acute symptoms. It is characteristic of that disorder and of no other intestinal disturbance. It is readily recognised by a microscopist of even small experience, and it furnishes a perfectly safe and reliable guide to appropriate treatment.

Application of the principles outlined above ensures an accurate and early differential diagnosis in dysentery, and in the case of bacillary dysentery makes it possible to apply specific treatment at the time when it will do the most good. It is equally accurate in amoebic dysentery.

The uncertainty and delay contingent on the diagnosis of bacillary dysentery by the method of bacteriological culture is abolished. For practical purposes of treatment, the method of cyto-diagnosis is more expeditious, more accurate and more dependable.

Cardiac Irregularities; especially with reference to Prognosis and Treatment.

By T. WARDROP GRIFFITH, C.M.G., M.D., F.R.C.P.,
British Med. J., October 18, 1924, p. 697.

AURICULAR fibrillation is a very common and serious form of irregularity.

We know that the presence of a pulse which has no recognizable rhythm, which is indeed non-rhythmic, carries with it the sure inference that it owes its lack of rhythm to this condition. The behaviour of the auricle is such that, while it loses all power of propulsion of the blood, it showers irregularly towards the auriculo-ventricular bridge hundreds of stimuli of which probably many never cross the bridge, and of those that do some may be so weak as not to elicit any response. Those that do cross and are strong enough to elicit a response reach the ventricle at irregular intervals, and, in harmony with the "all or nothing" behaviour of the heart pointed out by Bow-

ditch, the contractions will be the fullest efforts of which the ventricle is capable at those particular moments when the stimuli reach it. The condition may be detected only when for some reason a routine examination of the heart is made. On the other hand, the majority soon complain of dyspnoea and have the usual symptoms of cardiac failure combined with the characteristic non-rhythmic pulse with numerous imperfect beats, many of which do not reach the wrist even if they succeed in opening the aortic valve. We now know that the influence of digitalis in depressing the conductivity of the junctional tissues is especially developed in cases of auricular fibrillation, and that it is this property which makes it such a useful drug in the treatment of the cardiac failure with which it is associated. A large number of stimuli which would formerly have passed to the ventricles, goading them into contractions for which they were unprepared, are now arrested. Those stimuli which do reach the ventricles are separated by longer intervals; the ventricles have longer to recover and respond by stronger and more effective contractions. It is to be noted that the fibrillation of the auricles continues—indeed it is said that the use of digitalis tends to its perpetuation—and that the arrhythmia persists.

Dr. Griffith uses the tincture in doses of 10 minims every four hours or oftener. Sometimes the drug may cause a degree of heart-block which becomes complete, and in some cases during the development of this there have been no untoward symptoms; but this consumption should be avoided as excessive and not devoid of danger. When the action of the heart becomes infrequent under the influence of the drug, extra-systoles of ectopic origin begin to show themselves.

It is clear that in a certain number of cases the normal rhythm of the heart is restored by the use of quinidine. The answer to the question whether it should be used must depend upon the answers to the following: "What is the value of the restoration of the normal rhythm?" and "What are the dangers?"

The restoration of the normal rhythm will tend to equalize the amount of blood the ventricles have to deal with at each beat, and the regular call on their activities, one would think, must be favourable.

In harmony with these views, it is found that many of the patients express themselves as much better.

It is certainly the case that many unpleasant and some dangerous symptoms may arise after moderate doses of the drug, even when the precaution of test doses has been employed. Among these may be mentioned nausea, vomiting, palpitation, giddiness, faintness, flushing, convulsions, syncope, apnoea, dyspnoea, and other signs of cardiac failure. The selection of suitable cases is important. Those of short duration without great manifestations of cardiac failure do best, as might be expected.

The question of dealing with cases in which there are marked signs of cardiac failure is very important. It would seem best that these should be dealt with on the well understood methods of rest and digitalis, and that if thereafter it is deemed well to try to restore the normal rhythm, a period of at least a week should be allowed to elapse before the quinidine is begun.

In many cases the occurrence of extra-systoles is not noticed by the subjects of them, but they may be associated with feelings described as if a "beat were missed out" or as if the heart were "tumbling over." The amount of discomfort, in some cases amounting to distress, varies greatly; some pay little attention to them, others of a more nervous disposition suffer greatly.

Clearly to recognize that a cardiac irregularity is due to the occurrence of extra-systoles is of course a matter of prime importance. It is sometimes very difficult, and sometimes it is impossible, to be certain without instrumental means.

It is not easy to say anything useful about the prognosis of extra-systoles; in some cases they appear to

be of no importance, but it must be admitted that they are more frequent in those who have cardiac valvular or muscular lesions and in those the subjects of increased blood pressure, that they often persist in spite of treatment, that they may be associated with severe distress, that their very existence may develop a severe neurosis, and that the patient cannot be reassured.

In cases where we find no organic disease of the heart, we shall probably advise as to careful living with a strict avoidance of anything approaching to invalidism. Open-air pursuits should be encouraged and a reasonable amount of exercise should be taken. The diet should be light; mastication should be thorough, and the teeth should receive attention to make this possible, to eliminate oral sepsis, and to guard against flatulence. Coffee should be avoided; tea should be weak and fresh; tobacco should be limited. It is of interest to note that some observers claim to have seen great benefit from the use of small doses of quinidine in extra-systoles and in paroxysmal tachycardia. Fred M. Smith of Chicago is especially confident about this.

In Pulsus Alternans.—Every second beat is weak, and that without the excuse of being premature as in the case of the *pulsus bigeminus*. The prognosis of this is so grave that it is necessary to mention that a short period of alternans may follow on a premature systole without exciting alarm, but if it shows any tendency to persist the outlook at once becomes serious.

When heart-block is partial there may be no irregularity, as when every second auricular stimulus gets through.

When a patient has partial heart-block it may pass off entirely and the A-C interval may in time become normal; on the other hand, it may become complete, and then the patient is usually better in health and more comfortable than when the block was partial; both when the block is partial and when it is complete he is liable to attacks of the Adams-Stokes syndrome, and any one of these may prove fatal.

Dr. Frederick W. Price, M.D., F.R.S. (Edin.), regards extra-systoles as of great practical importance; they constitute one of the most frequent causes of irregularity of the pulse and may give rise to very disagreeable sensations. It should be remembered that while they are of more frequent occurrence in the middle-aged and elderly, they may be met with in the young.

The prognosis of extra-systoles is of great practical importance, and there is considerable diversity of opinion on this question. While it may be granted that extra-systoles are of more common occurrence in the subjects of organic heart disease than in those who are not, and are more frequent in myocardial degeneration than in valvular disease, further experience has not led Dr. Price to change the opinion he expressed in 1911—namely, that when extra-systoles are considered by themselves (that is, without reference to the conditions with which they may be associated) there is so far no evidence for supposing that they are either indicative of an impaired heart or that they add to the gravity of any existing morbid condition.

With regard to treatment; this should be directed in the first instance to the causal or associated condition, the general health, and any existing cardiac failure, if present. He had never found digitalis or quinidine of any value for the irregularity itself. Bromides are frequently of benefit for the associated subjective symptoms, especially when there is irritability of the nervous system or insomnia.

The Diabetes Problem of To-Day.

By ELLIOT P. JOSLIN, M.D., Boston.

Jour. American Med. Assoc., September 6, 1924.

FEWER cases of diabetes are appearing in the United States of America than formerly in young persons. The Jew is prone to diabetes not because he is a Jew,

but because he is fat. This is proved from life insurance statistics. Insulin has turned out to be more useful than was expected a year ago.

Many patients have been able to leave off insulin, probably partly because they pay more attention to their diet while using it. One great feature of insulin is the attention it directs to the all important question of diet. Possibly regeneration of the cells of Langerhans occurs in some cases. The duration of life in severe cases was much prolonged, but neglect of precautions is often fatal, especially as persons on insulin are tempted to use too liberal a diet.

Hyper-insulism.

By SEALE HARRIS, M.D., Birmingham, Ala.

Jour. American Med. Assoc., September 6, 1924.

DIABETES is a condition in which there is hypo-insulism with excess of blood sugar. Harris believes that some people suffer from hyper-insulism with defect of blood sugar, the symptoms being hunger, weakness and anxiety neuroses.

In some persons with these symptoms the blood sugar was found to be low, e.g., 0.065. After taking food five times daily, he has kept such patients quite free from symptoms for a year.

Sometimes the condition is associated with a lowered glucose tolerance.

In starvation this condition does not occur, the blood sugar being normal even with extreme emaciation.

The Use of Tryparsamide in the Treatment of General Paralysis.

By F. G. EBAUGH, M.D.,

and

R. W. DICKSON, M.D., Philadelphia.

Jl. American Med. Assoc., 13th September 1924, p. 803.

"Most syphilographers and clinicians have agreed that a new therapeutic approach is desirable in combating neurosyphilis, since the usual arsenicals and other drugs directed primarily from the spirocheticidal point of view are frequently ineffectual, owing to lack of penetrability of the central nervous system."

During the year 1922, 250 patients with general paralysis, fifty-two of whom were women, were admitted to the Philadelphia General Hospital psychopathic wards. In 1923, 218 patients, sixty-seven of whom were women, were admitted. This abundant material often represented failures of treatment, in that many of these patients had received the usual anti-syphilitic treatment in the hands of private physicians or in outpatient clinics. We may for practical purposes divide this large group of material into three main classes.

A. *The Organic Group*.—Parenchymatous neurosyphilis in which the destruction of the central nervous system has proceeded beyond repair. These patients showed definite mental deterioration. Eleven patients of this type were treated.

B. *Organic Reaction with Psychoses of Functional Coloring*.—General paralysis in which therapy may possibly arrest the pathological processes and restore the patient for either transient or permanent periods. Clinically, this group includes the psychoses simulating the functional disturbances seen in maniac excitements with expansive delusions; in the depressions, and in other reaction types, in addition to the organic syndrome present in general paralysis.

The use of tryparsamide in the thirty-six cases of this type treated was of great interest and clinical import, as many of the patients had previously received arsphenamin treatment without success.

C. Transitory Psychoses Without Signs of Deterioration.—General paralysis in which the mental symptoms are frequently transitory and are exhibited before any signs of deterioration develop. In this group occur the delirious reactions and neurologically irritative phenomena, as seen in convulsive seizures, aphasic attacks and meningovascular and endarteritic upsets. Such patients are so few that their admission to the psychopathic ward was a rare occurrence. However, a small number of patients were admitted showing delirious reactions. Five cases were chosen for treatment.

Tryparsamide was given intravenously in weekly doses of 3 gm. (in a solution in 10 c.c. of sterile distilled water) over a period of ten weeks. A rest period of eight weeks was instituted after each course of ten injections. Careful preliminary ophthalmological studies were made in each case, and optic atrophy of any degree was ruled out. Routine laboratory studies, including blood-chemistry and urine, were normal in each case. A weight chart was kept of each patient, as well as frequent progress notes regarding clinical and serological changes following treatment.

Although mercuric salicylate was given in the first ten cases, this was discontinued owing to complaints from the patient concerning the pain of injection. At any rate, for the purposes of the investigation, it seemed advisable not to use both drugs in treatment in order that definite data could be obtained concerning the value of tryparsamide.

The authors define improvement in this group to mean that the patients have been discharged from the psychopathic wards and are working regularly and are supporting themselves or their families.

Summary of cases.

General Paralysis.	Number treated.	Number improved.
Group A. Deteriorated cases	.. 11	0
Group B. Organic psychoses with functional coloring	.. 36	10
Group C. Transitory psychoses	.. 5	5
Total	.. 52	15

The serological results were interesting in that in all cases the cell count and the globulin fell within normal limits following the first course of injections. The gold curve tended to show less precipitation. The spinal fluid Wassermann reaction, however, remained unaltered in nearly every case.

There was a marked improvement in the physical condition of the entire group of patients treated. In two-thirds of these cases, this consisted in a definite gain in weight, and an increased hematopoiesis as shown in increased hemoglobin and red blood cell counts.

Untoward effects of tryparsamide.

In the treatment of these patients, approximately 1,000 intravenous injections have been made, and the unfavourable results summarized as follows:

1. Jaundice developing after injections in two cases.
2. Dermatitis in one case.
3. Visual disturbances.
4. The serious question of neuro-relapse.

The jaundice in the two cases occurred during the second course of injections. In one case it was mild, and after two weeks' rest treatment was again instituted with no bad results. In another case it was very severe, with definite evidence of impairment of liver function.

The dermatitis, in contrast to that seen after arsphenamin therapy, was certainly mild, and the patient has now completed a course of tryparsamide with no returns of her skin condition. This finding is therefore of little clinical import.

Since tryparsamide has a selective affect for the optic tract and can never be used with any degree of optic atrophy, its universal use in general paralysis has been seriously impaired. To the authors' surprise, routine ophthalmological consultations have ruled out the therapeutic use of this drug in nearly one-third of the cases selected for treatment. This was discouraging, since these patients frequently were considered otherwise favourable for treatment after complete clinical and serological examinations.

The fact that out of the fifty-two patients treated fifteen are now working is most gratifying, especially as eleven of the fifty-two cases were deteriorated.

The question of neuro-relapse impresses the authors as being a very important one, and they certainly do not wish to duplicate their recent experiences with two of the patients treated. However, as in arsphenamin therapy, the patients in whom these upsets occurred responded to further treatment. The frequency of reactions of this type in the further use of tryparsamide will prove of extreme clinical importance. One should not speak of a cure in neurosyphilis, and therapy is directed more to arrest this disease before mental deterioration has developed.

At present, they definitely conclude that tryparsamide gives evidence of being the best drug so far advanced in the treatment of general paralysis. They do not feel that a general release of this drug should be made now, since many physicians would begin to use it in primary and secondary types of syphilis, in which it would prove to be valueless.

Report of the Third Session of the Health Committee of the League of Nations.

THE Committee sat at Geneva from September 27th to October 4th, 1924, and was attended by delegates from all nations excepting Russia. India was not directly represented, her interests being looked after by the British delegate, Sir George Buchanan.

Of matters interesting to us in India, the Health Committee approved the preparatory work for the opening of an Epidemiological Intelligence Office at Singapore, and notably, the summoning of a conference of the health officials of Eastern countries to be held at Singapore this year. The object of this office is to quicken and improve the interchange of information regarding epidemic diseases between Eastern countries.

The Health Committee approved the report of a sub-committee on opium. This report was asked for by the Preparatory Committee of the International Opium Conference. The sub-committee stated that the legitimate requirements of European populations might be taken as 450 milligrammes of raw opium and 7 milligrammes of cocaine per head per year. The Health Committee further agreed that it was doubtful if the therapeutic value of heroin was sufficient to justify its manufacture in view of the abuse this drug is put to.

Another sub-committee had been at work studying the possibility of disinfecting skins and hides against anthrax. No economical and certain method has yet been devised which is not detrimental to the material. The matter is one of great importance to India as the International Labour Office are keeping a sharp eye on the Indian hide trade.

Reports of the various commissions at work under the auspices of the League of Nations were received and discussed; notably the malaria commission now at work in Europe, the anti-tuberculosis and sleeping sickness commissions now at work in equatorial Africa.

Finally, the Committee decided to continue the interchange of personnel between nations and to finance the scheme for 1925. Under this scheme health officials of one nation have brief visits of study to other countries.

As can be seen from the minutes of this third session, the Health Organisation of the League of Nations is

a live and active body supported by ample funds. It is unfortunate that it is not yet possible to amalgamate it with the old established Office Internationale d'Hygiène Publique as the functions of the two bodies are identical, but until the League of Nations is firmly established as the leading international court it will not be possible to do without the "Office."

Radiotherapeutics in Dermatology.

British Med. J., 20th September 1924, p. 512.

In the section of dermatology of the British Medical Association meeting there was a discussion on radiotherapeutics in dermatology. The opening paper was by Dr. J. H. Sequeira. He recorded several types of dermatosis for which he found *x*-ray therapy of value:—

(1) *For the relief of Itching and in Pruriginous Skin Diseases.*—Pruritus ani and pruritus vulvæ in which no local cause can be discovered are frequently relieved by occasional exposures. As a rule benefit is manifest after the first sitting, and if there is not speedy relief it is unwise to persist with the rays. Eczematous lesions, often due to scratching, in which conditions are benefited not only by relieving the pruritus, but by the local action of the rays. In all cases he allows an interval of three weeks between successive exposures.

(2) *In Psoriasis and Chronic Seborrhoides.*—Where the eruption in psoriasis is limited an occasional *x*-ray treatment is of great value. The lesions rapidly disappear, but the tendency to relapse is not removed. In some forms of seborrhœic dermatitis the *x*-rays have a rapidly beneficial effect: moist lesions dry up, scaly lesions disappear. Where the scalp is badly affected the depilatory action of the rays may be used with advantage, the removal of the hair permitting more thorough treatment by topical remedies.

Tuberculosis.—The first cutaneous disease treated by the *x*-rays was lupus vulgaris, and though no one can deny that the results are beneficial in certain types of case, much harm has been done in others. In the ulcerative form and in the closely allied condition, scrofuloderma due to infection of the skin by the breaking down of tuberculous foci in glands, bones, and joints, the *x*-rays are of great service. A few applications at intervals produce a rapid healing of the ulceration and the disappearance of gumma-like swellings. After the ulcers have healed it is common to find isolated dry nodules in the cicatrix, and these require treatment on the same lines as dry lupus. In dry lupus the nodules are yellowish-brown spots of translucent jelly-like appearance, embedded in the skin. There may be a thickening of the horny layer over these nodules. This type can only be removed by the *x*-rays by pushing the treatment to an actual dermatitis, and after treatment pushed to this extreme, or repetition of the *x*-ray applications over several years (a not uncommon thing), we meet with the tragedy of lupus carcinoma.

Granulomata.—Granuloma (mycosis) fungoides was first treated by the *x*-rays by the late Dr. Allan Jamieson. There is no other condition in which such striking results are obtained. Large mycotic tumours disappear in a remarkable manner, areas of infiltrated skin become soft and supple, and the intolerable itching is allayed. Unfortunately the improvement is only temporary, the infiltration and tumour formation return. By repeated treatments the patient's life is prolonged, much suffering is relieved, and we are able to avoid the distress and discomfort produced by septic ulceration of fungating masses, which was usual before the introduction of radiotherapy.

Carcinoma of the Skin.—Many admirable results have been obtained. The earlier diagnosis of rodent ulcer has led to an almost complete disappearance of the grave cases, formerly so common in the clinics. Radium has been used in 1,262 cases, and small rodent ulcers not involving bone or cartilage can usually be cleared up by

three exposures of two hours' duration, to a half-strength radium plate. Where bone is involved the *x*-rays in heavy doses may be used in conjunction with surgery.

Squamous carcinoma does not respond to *x*-ray or radium treatment, and in no case would the author recommend either measure instead of operation.

Appendages of the Skin.

Ringworm of the Scalp and Beard.—The depilatory effect of the *x*-rays led to their use in tinea. Thanks to Sabouraud and Noiré's pastille and to the tintometer of Corbett and Dean, and to the exact regulation of distances which we owe to Kienböck and Adamson, the technique for epilation of the scalp in tinea capitis can be carried out with precision. In Dr. Sequeira's clinic 7,143 cases have been treated during the past fourteen years. In only four cases has he been able to trace a partial alopecia, and this may have been due to idiosyncrasy.

There is no risk whatever to the brain, and in a large proportion of cases the hair grows stronger and thicker after the epilation. As a rule no children under 4 years of age are treated. The results in tinea barbæ are equally good. It must be quite understood that the rays do not kill the fungus; they merely bring out the infected hair. It is, however, interesting to note that eczematoid ringworm of the extremities is often benefited by a short exposure to the rays.

In a few early cases of coccogenic sycosis a cure is obtained, but in many cases epilation produced by the *x*-rays produces only a temporary improvement in the condition. Relapses are exceedingly common in the chronic cases. In some instances one is obliged to produce a permanent epilation before a cure is effected. This is often followed by atrophy and a vulnerability of the skin leading to recurrent inflammation, especially on exposure.

Hypertrichosis.—Many dermatologists have used the *x*-rays for the removal of superfluous hair, and at one time an improved technique appeared to give most gratifying results. Unfortunately, in a certain proportion of cases, the removal of the hair permanently has been followed by the appearance of slight atrophy with ugly telangiectases on the radiated skin and on the mucous membrane of the lips.

General Effects.

*Influence of *x*-rays on the Viscera and Blood.*—It is important for the dermatologist using *x*-rays to be aware of the influence of these radiations on certain organs and on the blood. It is generally known that the seminiferous tubes of the testes are exceedingly sensitive, and that sterility, complete or partial, temporary or permanent, may follow exposure of the testes to the rays, especially if repeated. Radium acts similarly. The rays also have an undoubted influence on the thyroid gland, and this fact has been utilized in the treatment of Graves's disease. *X*-rays and radium, especially in cumulative doses, have a marked influence on the blood. Senn was the first to show that an enlarged spleen and glands in leukaemia will diminish under *x*-ray treatment, and the leucocytic count is materially diminished. All workers with the *x*-rays should study Sir Humphry Rolleston's admirable and timely address on acute constitutional symptoms due to radiations. He concludes that these symptoms are probably due to flooding of the circulation with proteins liberated by the destruction of cells.

Phototherapy showed by experiment that the various parts of the spectrum (visible and invisible) have different properties. It was demonstrated by simple experiments that the so-called sunburn is a reaction of the skin to the actinic rays of light. Actinic light has very little penetrative power, and penetration of vascular tissues is very small indeed. By experiment Finsen showed that the red colouring matter of the

blood is an important factor in preventing this penetration. The shorter radiations penetrate less than those of longer amplitude. For therapeutic purposes the greatest penetration is obtained by concentrated sunlight, or, what is more convenient in northern latitudes, concentrated rays from a powerful carbon arc, on a surface rendered anæmic by compression. The heat rays of the sun or arc light must be removed by a cooling apparatus, which is in practice combined with the compressor.

(a) Local Effects on the Skin.

About six hours after the exposure of an area to concentrated arc light for an hour an acute erythema occurs. This is followed by vesication, and the vesicles may take several days to heal.

Lupus Vulgaris.—Finsen therapy is the ideal method of dealing with cases of lupus vulgaris of the dry type, especially where the lesions are situated, as in the majority of cases, on the face, and it is important to obtain a good cosmetic result; from 60 to 70 per cent. of cases of lupus are cured by Finsen therapy—that is, local application of concentrated light alone.

(b) General Effects of Light.

Like the x-rays, the sun's rays and the radiations from a powerful artificial illuminant have a marked influence on the human body generally. Fortunately, there is here to record very little but what is good. The exposure of the whole surface of the body to the sun's rays, as shown by Bernhard and Rollier in the Higher Alps and by Gauvain at Alton and Hayling, is of great therapeutic value in certain forms of tuberculosis.

The exposure of the whole body to light in the light bath produces:

(1) Erythema in the irradiated area. This is usually transitory, and may be followed by desquamation.

(2) Pigmentation. The degree varies with the duration and number of exposures, and with the individual. The source of light also has an influence.

(3) A moderate increase in the body weight, observed in some cases.

(4) A slight increase in the leucocytes was noticed in some patients.

(5) An increase in the bactericidal action of the blood; but in some instances there is no change, and it seems probable that this observation may have a prognostic significance (Colebrook).

(6) Steady improvement and actual healing, without local treatment, of surgical tuberculosis and especially of lupus vulgaris, both of the skin and mucous membranes. In lupus the combination of local light treatment (Finsen therapy) with the light bath gives 90 per cent. of cures. Experience in this respect agrees with that of Reyn and his assistants.

(7) A marked improvement in the general health of the patients, although Dr. Argyll Campbell found no change in the basal metabolism of patients examined.

The only untoward result seen in light bath treatment, whether the illuminant is the sun or an artificial source, is the occasional "flare up" of a tuberculous process, especially where there is pyrexia.

It is wise to begin the treatment of cases of visceral tuberculosis with very short exposures limited to small areas, and to watch carefully the effect on the temperature and other symptoms.

Dr Rupert Hallam (Sheffield) was rather surprised that Dr. Sequeira had not mentioned the value of small doses of x-rays in the treatment of that group of diseases which at one time sheltered under the name of eczema.

Notes from the Journal of the American Medical Association, 6th December, 1924.

(1) Drs. Wile and Wieder of Michigan report further successes in the treatment of neuro-syphilis by try-

parsamide. Marked improvement often results, but the authors do not claim cures.

(2) Dr. Stokes and Dr. Schaffer of Rochester report that a course of treatment consisting of (a) arsphenamin intravenously, (b) soluble mercurial salts intramuscularly and (c) sodium iodide intravenously; combined with mercurial inunctions during the periods of rest between the courses of injections, have given excellent results in 90 per cent. of cases of meningelial neuro-syphilis, in 75 per cent. of cerebro-spinal syphilis, in 48 per cent. of tabetic neuro-syphilis, and 39 per cent. of vascular syphilis. In general paralysis these methods gave no permanent benefit.

The arsphenamin course consisted of six doses once weekly (1110 gram for each 25 lbs. of body weight). Mercuric succinimide was given simultaneously for 20 to 30 daily doses. The interim treatment was forty inunctions of 30 to 50 grains, with rest intervals of a month between each set of inunctions. The iodide treatment was 1 to 10 grams of sodium iodide daily for 20 to 30 injections. In some cases the arsphenamin course was intensified by giving the injections twice weekly for 8 weeks, and in some intraspinal arsphenaminised-serum was given.

(3) Dr. Nelson Myll (Major, U. S. Medical Corps) combats the view that genito-urinary tuberculosis should be treated surgically. He advocates a course of treatment of at least a year consisting of:—(1) Rest in bed in the open air. (2) Heliotherapy by the Rollier method, the sites of the inflammation where possible receiving direct radiation. Tanning of the exposed part short of burning is to be aimed at. (3) A generous, nutritious diet.

In cases with bladder irritation 5 c.c. of a 5 per cent. solution of calcium chloride was given intravenously every five days.

Abscesses are aspirated or opened and exposed to the light. At the beginning of the treatment there is often a temporary aggravation of the local symptoms, but steady improvement is almost invariable.

The International Public Health Committee of the Bureau International. October, 1924 Session.

THE session was held in Paris from the 6th to the 15th October, 1924, and was attended by delegates from some 30 different countries and states. In addition to general business and agenda, the following special questions were discussed.

Plague.—Reports were received from many countries as to the rodent hosts and transmitting fleas responsible for epidemics. In the localised outbreak in East Suffolk in 1909-1910, in addition to rats, two hares, two rabbits and a cat had been found infected. A report received from Algiers on the results of examination of 900,000 rats and their ecto-parasites shewed that there were very marked differences in the species most prevalent in different departments, but *Mus decumanus* constituted 74 per cent. of the general rat population, and *Xenopsylla cheopis* was the most prevalent rat flea. In Senegal this flea constituted no less than 95 per cent. of those found on the local rats. In Lisbon, *Ceratophyllus fasciatus* had been incriminated as a plague-transmitting flea in cold climates. Professor Gosio reported that he had found that larvae of the common flies *Musca domestica*, *Calliphora vomitoria* and *Lucilia macellaria*, developing in plague-infected corpses, shewed plague bacilli in abundance in their intestinal tracts, and the infection persisted through pupation into the adult fly. An account was given of the 1920-21 epidemic in Manchuria, responsible for some 8,000 deaths. The tarabagan *Arctomys bobac*, commenced as a purely bubonic one, terminated as a purely pulmonary one, with direct transmission via the sputum from man to man. In India the recrudescence

in 1923 in the United Provinces and the Punjab was dealt with, together with the relative immunity enjoyed by Bengal and Assam. In an outbreak in Madagascar 65 per cent. of cases were either of septicæmic or pulmonary type, all of which proved fatal.

All the observations made tended to confirm the view of the unity of the plague virus and to discredit the view that pneumonic plague was due to symbiosis of *Bacillus pestis* with other pulmonary organisms, such as the influenza bacillus.

Scarlet Fever.—Reports received from different countries indicated that there was a steady reduction in mortality of recent years. Thus the Low Countries (Holland and Belgium) reported a diminution in mortality in 30 years from 5.57 per 10,000 inhabitants to 0.78 per 10,000 inhabitants. In Spain the corresponding reduction was from 0.67 in 1900 to 0.22 in 1923. In Japan the disease, once rare, was now not uncommon. In Uruguay there had been extensive and severe epidemics, but mortality tended to be very much reduced of recent years. A report from India stated that the disease was very rare indeed among Indians; it was seen especially among the families of British troops in this country, but was an insignificant disease as far as India is concerned.

Alastrim.—The independent existence of this disease, as one differing from small-pox, was discussed. In Switzerland small-pox appeared of recent years to have undergone considerable loss of virulence, cases tending to be of very benign type. An extensive epidemic of alastrim occurred in the island of San-Miguel in the Azores in 1923-24. The infection was imported from over-seas and spread over the entire island, despite all protective measures. In ten months there were 15,000 cases out of a total population of 126,000 in the island, but with only 10 deaths, three of which occurred in pregnant women. The train of symptoms appeared to exclude small-pox. In general there was slight fever for only two to three days; slight headache and joint pains; vomiting was rare; and the rash appeared as the fever subsided. It was at first papular, then vesicular; then the vesicles became milky in colour, "milk-pox"; whilst the eruption was practically never confluent. It lasted 24 to 48 hours, sometimes several days, after which desiccation was rapid, leaving finally only the very slightest of whitish scars. The size of the vesicles varied from that of a grain of wheat to that of a pea. The face, feet and hands were especially affected, but the patients' general health remained excellent and they were not inconvenienced by the eruption.

In brief the disease appeared to be quite unlike small-pox. Umbilication of the vesicles was very rare; they resembled those of chicken-pox rather, and were dome-shaped. Vaccination was found valuable as a protective measure. In general it might be concluded that small-pox, alastrim, cow-pox and varicella were members of the same family of diseases, but equally stringent prophylactic measures should be taken against all four types of disease.

Leprosy.—A recent census in Italy had brought only 182 cases to light in the 34 provinces, some of which were soldiers returned from Albania, who appeared to have contracted the infection in the trenches there during the war. In the Dutch East Indian colonies leprosy was becoming a serious problem; thus in Surinam there were 1,500 lepers in a population of 130,000. In India the estimated general incidence was some one per cent. Korea had 3,000 to 4,000 lepers. Algiers presented an interesting contrast; during the past 30 years only about a dozen cases had been reported among the indigenous inhabitants, whereas 150 had occurred among the European population, three-quarters of them among Spaniards in the provinces of Valence and d'Alicante.

Goitre.—Propaganda was in progress throughout Switzerland to persuade the population to add 2.5 to 5 mgms. of potassium iodide per kilo. to their kitchen salt in order to control the endemic goitre so prevalent

in the country. No harmful results had occurred from this measure, whilst in cows the addition of potassium iodide to the salt used in feeding appeared to increase their milk output.

Tabes and General Paralysis.—Reports indicated the very varying difference of incidence in different countries and climates, also in European countries diminished virulence of type in recent years,—probably owing to recent improvements in the diagnosis and treatment of syphilis. In Sweden, however, the incidence of tabes in 1915-1919 was definitely higher than in 1910-1914, or for any previous period within the past 60 years.

Sleeping Sickness.—During the past 20 years sleeping sickness has invaded the Portuguese islands of San Thome and du'Prince, and also Angola and Mozambique on the mainland. In the Cameroons the French have now a full and very efficient organisation to combat the disease, and progressive diminution in incidence is reported month by month.

Rhinoscleroma was reported as prevalent in certain areas in Poland, especially in the south and east. In Galicia it had long been known, three different foci being recognised, one in the east, a second around Lwow, and the third in western Galicia. The age incidence was between 15 and 50 years, and 59 per cent. of the cases were among industrial workers.

Among many other projects in which the Committee were interested were such questions as the distribution of typhus and relapsing fever in India; the climatic and racial incidence of cancer; the mutations of the tubercle bacillus with special reference to prophylactic antigens; pulmonary tuberculosis in Cochin-china and Indo-china; and prophylaxis against kala-azar.

The Public Health Commissioner with the Government of India, in forwarding the report of the Bureau, writes that every attempt is being made to make the connection between India and the Bureau closer, and a delegate or delegates specially representing India and in close contact with the present public health problems of India will be appointed.

Sea-Sickness.

In the *British Medical Journal* of the 13th December, 1924, Dr. A. P. Bertwistle, M.B., Ch.B., F.R.C.S. (Ed.), advocates the following prescription for this distressing malady; Sodii bicarb. grs. xv.; tinct. gentian m.xx.; spir. chlorof. m.xx.; aquam ad oz. one half; one tablespoonful every four hours or more often. It is claimed that beneficial and even dramatic results ensue. The mixture is tolerated even when the patient is actually sick; if vomited it serves to wash out the stomach; and it is perfectly harmless, which can hardly be said of chloral if pushed to the point of somnolence.

The Sex Ratio among the Chinese.

As is well known, Great Britain is faced with the problem of what to do with her one and a quarter million surplus females, and various remedies, from polygamy to emigration, have been suggested. In an exceedingly interesting lecture before the China Society of Science and Arts, Dr. F. Oppenheim has shewn that exactly reverse conditions exist in China; (*The China Journal of Science and Arts*, September, 1924, p. 466). In England for the period 1906 to 1915 male to female births were as 103.9 to 100; but an excess of male deaths occurs during the first year of life, 124.3 male infants dying as against 100 female infants. For this excess male mortality he adduces an interesting reason. It has been shewn by Morgan, Stevens, Wilson and others that sex is determined by the presence or absence of an additional chromosome in the spermatozoon. The female is homozygous, and in the ovum there is no additional chromosome; in other words, the female

produces only one kind of germ cell. The male, on the other hand, is heterozygous, and produces two kinds of germ cells, one with, the other without, the additional chromosome. If pairing of ovum and spermatozoon results in the presence of the additional chromosome, the offspring is female; if not, the offspring is a male. Further, as hereditary characters are transmitted through the female only and not through the male, as in the well known instances of hemophilia and colour-blindness, inherently lethal factors are probably thus transmitted and manifest themselves in the male child, who thus shews a greater tendency to die than does the female; in the female offspring such factors are probably compensated for by the presence of the additional chromosome, and the inherent lethal factors do not become manifest in them, but only in their male children. This results in the excess mortality among males as compared with female infants, and in most European countries in an excess of females among the adult population.

In Germany, since the war terminated, there has been a marked rise in male births, the proportion of male to every 100 female births having risen steadily from 106.2 in 1914 to 107.7 in 1918, and 107.8 in 1921,—the latest figure quoted by the author; who discusses the reasons for this well known post-war phenomenon, and concludes that it is due to the conditions of mal-nutrition following upon the close of the war.

It is interesting to note that, when general infant mortality is high—as in a hot summer, from infant diarrhoea,—the curve of infant male mortality is the inverse of the general infant mortality; males are not especially affected; and such factors as are responsible for the excess male infant mortality in general are not external or climatic factors; but inherent and inherited ones.

Turning to conditions in China, the author first records the result of an investigation of living brothers and sisters of 473 adolescent Chinese students. The results were to show 115.6 males as against 100 females. Further, the curious fact appeared that in China infant mortality is in excess among females, and not males. (The author does not discuss the possibility of female infanticide as an explanation of this, but—in view of the disclosures in the recent census of India—we consider that such a possibility in China would be worth investigation.) The female infant mortality was 38.1 per cent. as against a rate of 32.6 per cent for males. Similar findings are recorded from an investigation of 1,000 Chinese mothers in Peking by Dr. Gray, and of 4,000 fathers by Dr. Lennox in Peking. On the other hand, among the Chinese in Singapore, where females are relatively few and economic conditions good, the female death rate, 2.9 per cent., is lower than the male death rate, 3.8 per cent.

"If we now summarise the results," concludes Dr. Oppenheim, "we find two very interesting facts; firstly, the excess of male births is greater in China than in any other country of the world where statistics exist; secondly, this excess of males even increases during the childhood period, because the death rate of the girls in China is higher than that of the boys." Thus China presents an interesting and unique contrast to the rest of the world. At the matrimonial age there are 125.6 bachelors to every 100 spinsters, and apparently one male in every five has no chance of marriage. Where does this surplus male population go? The reply is that it emigrates to the Straits Settlements, the Dutch East Indies, the Philippine Islands and Siberia; where, under good economic conditions and with a paucity of females accompanying it, conditions are reversed and come to resemble those of Europe.

A Chemical Basis for the Treatment of Tuberculosis.

In the *American Review of Tuberculosis* for August, 1924, Drs. Louise G. Robinovitch and G. W. Stiles, Jr.,

record encouraging results in the study of this subject. The dominating fact which makes the tubercle bacillus so resistant to treatment is its waxy or fatty envelope, an envelope which, according to Wells, de Witt and Long is not truly fatty but is for the most part an ester or mixture of esters of the group of waxes. In reviewing the literature to date in 1923 the same authors conclude that "no specific chemotherapeutic agent has yet been found for tuberculosis."

Dr. Robinovitch commenced the present series of studies in 1921; investigating first the value or otherwise of radio-active salts such as thorium hydroxide and nitrate, and later oxygen, but with negative results, although ozone or activated oxygen gave some promise of proving useful. The tubercle bacillus grows best in an acid medium, whereas an alkaline medium appears to be unfavourable to it. Steapsin or lipase, alkalised and mixed with a strong co-hydrolyzer of wax, was found to decorticate the bacillus; whilst an insulin mixture, similar to the lipase mixture, also decorticated it. It seems possible therefore to devise therapeutic measures in which tubercle bacilli in the body might be rendered susceptible to the destructive action of steapsin or insulin, and further experiments on these lines with ozone and activated oxygen, obtained from calcium hypochlorite, are in progress. Also experiments are under way in which tubercle bacilli, subjected to the decortivating action of steapsin and insulin, with chloroform as a co-hydrolyzer, are being tested for their antigenic properties.

The Diagnosis of Cancer.

Jour. American Med. Assoc., January 3rd, 1925.

DR. JAMES EWING, Professor of Pathology of the Cornell University Medical College, has an article on this subject which is well worth study both by pathologists and clinicians.

He insists that a mere microscopical examination of the tissues is not enough, especially if the rapid frozen section method is adopted. Not merely full clinical details of the case are needed; the pathologist, if his report is to be of value, must have an opportunity of examining the patient in collaboration with the surgeon. "Having made more errors by the frozen section method in breast cases than by the gross examination, I have not resorted to frozen sections in this field for many years, but rely entirely on gross inspection of the breast tissue."

It is refreshing to find such candour on the part of a highly experienced pathologist and this confession should be taken to heart by the surgeon who too often takes refuge in the supposed infallibility of the pathological report.

Many pathologists who read this illuminating article will feel in the same frame of mind as the successful barber surgeon who had had many years of success in cutting for stone and who was dismayed when he saw for the first time a demonstration of the blood vessels of the parts through which he was accustomed to cut with supreme indifference. The diagnosis of malignancy is a subject of great difficulty demanding special study and vast experience such as few have the opportunity of acquiring. In the meantime it is essential that the clinical features of the disease should be studied with the greatest care and that due importance should be attached to them before a judgment is formed.

The Management of Exophthalmic Goitre.

By J. MARION READ, M.D., San Francisco,
N. American Med. Assoc.,

December 20th, 1924, p. 1963.

EXOPHTHALMIC goitre is a disease whose aetiology is as yet unknown. This fact renders impossible the

prosecution of rational therapy and forces us to the employment of empirical methods. It is essential to recognize that exophthalmic goitre runs a fairly definite course and in the majority of cases results in spontaneous cure. Failure to recognize this fundamental principle has led to great confusion and uncertainty in the minds of most physicians as to the proper course to follow. Some of the predisposing and exciting factors seem fairly well established. First of these is heredity. The exciting causes may be grouped under three heads:—sex epochs, psychic trauma, and infection, with its drain on the protective mechanism.

The term hyper-thyroidism has become more firmly entrenched since the recent developments in basal metabolism. Unfortunately, it has become the custom to express the basal metabolic rate in percentage variations above or below a supposed normal instead of using absolute values, as has always been done, for example, in recording body temperature.

Failure to secure uniformly satisfactory results with methods based on this theory, together with an increasing number of clinical and experimental facts that defy interpretation on this basis, has cast much doubt on the validity of the "hyperthyroidism theory." The taboo against iodine, instituted by Kocher and fostered chiefly by the proponents of the hyper-thyroidism theory, has been lifted, and a useful drug, whose limitations we should soon know, finds its place in the treatment of exophthalmic goitre.

The very best surgical results, until very recently, show a mortality of 4 per cent. which is no greater than obtains with any surgical operation of equal severity, but is still twice the natural mortality rate of this disease. An excellent check on the natural mortality rate has recently been afforded by the investigations carried on at the Mount Sinai Hospital in New York, in which fifty patients were treated with no specific measures other than small doses of syrup of ferrous iodide administered in some cases. The mortality rate from exophthalmic goitre in these cases was 4 per cent. The number cured and improved compared favourably with the best results of surgical treatment.

These observations are of tremendous significance from a therapeutic point of view, for they establish the fact that with moderate rest in bed small doses of iodine and symptomatic treatment there is a strong tendency toward spontaneous cure. Exophthalmic goitre tends to run a fairly definite course which it is difficult to shorten appreciably by any known means, including surgery and Roentgen rays.

Exophthalmic goitre represents a physiological or functional disturbance in which both the endocrine and autonomic nervous systems participate. The thyroid function is only one of many that are deranged. All this evidence seems to indicate that this disease is not one of the thyroid *sui generis*, as neither gross nor microscopic changes in that gland are constantly present. For this reason measures directed toward the thyroid alone can only result beneficially in so far as the thyroid participates in the disease. For this reason neither surgery nor Roentgen ray exposures of the thyroid can be regarded as curative. That these measures do not fulfil our hopes is evidenced by the facts, if one tries to judge them in an impartial light.

All this might imply a fatalistic point of view in which therapeutic nihilism figures prominently. But such is not the case, as will presently be shown, for there is much that can be done for these patients.

Rest in bed is necessary when the patient first comes under observation, in order to obtain approximately basal conditions on which a satisfactory estimate of the severity of the disease may be made. The amount of rest should vary directly with the severity of the disease, as measured by the toxic manifestations and basal metabolic rate. In severe cases the weakness is such as to enforce rest in bed. As the patient improves,

more and more activity may be allowed, as these patients are restless and feel better if allowed to do something.

More important than rest in bed is avoidance of mental stress and strain, such as is occasioned by worry and responsibility. In this connection we should stress the necessity of relieving constipation with its intoxication. McCarrison's theories on the ætiology of exophthalmic goitre are interesting in this connection.

Loss of weight is a prominent feature, which is not difficult to prevent under proper management. Most patients have a good appetite; in fact in some it is insatiable. As a rule weight is regained when some attention is given to the patient. The aim should be to maintain the normal weight of the individual or the standard weight for the patient's height.

One of the symptoms most frequently complained of and the one most distressing to the patient is palpitation. The most useful drugs in this connection are quinine hydrobromide or quinidine.

The danger of serious and permanent cardiac damage is often used as a reason for early and radical surgical intervention, but full knowledge of all the facts will probably show that the danger is much exaggerated. With the growing tendency to view this disease as representing probably a qualitative change in the thyroid secretion, the giving of iodine has become more popular.

The response varies in different individuals and a few do not tolerate it, while others show marked improvement. The beneficial results will be manifested by early abatement of those symptoms which may be interpreted as due to toxæmia. Decrease in the pulse rate is usually the first objective sign. Subsidence of tremor and a subjective feeling of well-being are often noted, together with a drop in the basal metabolic rate.

Compound solution of iodine is recommended by the Mayo workers. Potassium iodide may also be used. If compound solution of iodine is used, from 3 to 5 drops a day should be the initial dose to test the individual's tolerance. This may then be increased to from 10 to 12 drops daily. Roentgen ray irradiation should be tried in most cases of exophthalmic goitre, as it seems to reduce the toxicity, and in skilled hands is without danger.

The period of treatment varies with the severity of the disease and should be persisted in from four to six months, with monthly estimation of the basal metabolic rate. The half-hearted pursuit of this method has led to its incorrect evaluation by the profession and to unsatisfactory results to the patient. In more than fifty cases treated at St. Luke's Hospital in the last three years, there have been no deaths from Roentgen ray irradiation alone. While no myxœdemas have resulted from Roentgen ray irradiation alone, three have occurred in patients who have been operated on after Roentgen ray irradiation had been started.

Surgery must be resorted to in cases of mechanical obstruction, such as substernal thyroid participating in the exophthalmic goitre and severely toxic cases that show little or no improvement after from four to six months' trial with other measures.

Quinidine in Cardiac Disease.

AN editorial in the *Therapeutic Gazette* of January 15th, 1925, deals with this subject. The following is an extract from the article:—

About a year ago the Cardiac Club of Edinburgh decided, after a discussion of the value of quinidine for fibrillation, to make a collective investigation concerning its usefulness, and in a recent issue of the *Lancet* Hay has combined the reports which were sent in. There were 166 patients suffering from auricular fibrillation and valvular disease of the heart, and 87 patients with the same condition but no valvular disease. Naturally, amongst these individuals there

were cases of arterio-sclerosis and myocardial degeneration, high blood pressure, and syphilitic infection, with or without valvular lesion. There were also 12 thyrotoxic cases. One of the difficulties met with by Hay was the proper classification of the patients, partly because the method of administration of the quinidine varied so greatly; thus one practitioner gave 5 grains three times a day, increasing to 7 and later to 10. Others, on the other hand, gave the same dose five times a day or 25 grains in four days, and gave digitalis first to slow the heart, or gave it concurrently with the quinidine. Naturally it is difficult to compare cases having such variance in treatment.

So too, there was a lack of uniformity in treatment after the resumption of sinus rhythm. Some of the reporters followed the method of gradually reducing the dose of quinidine, and others stopped it at once as soon as fibrillation was arrested. Still others reported upon the liability to relapse, finding that even massive doses failed to prevent recurrence. Taking it all in all, the general opinion seems to be that quinidine should be continued for some time after normal rhythm is restored. The cases furthermore could be divided into those in which there was complete failure, others in which there was temporary success, and others in which the results were permanent in the sense that normal rhythm was restored up to the date at which the report was made. It failed completely in 109, succeeded temporarily in 67, which means 176 ultimate failures, and was a permanent success in 89.

Passing on to a consideration of the safety of quinidine, Hay and his co-workers well recognize its dangers. Amongst the 286 patients, headache, nausea, vomiting, diarrhoea, abdominal pain, dizziness, faintness, buzzing in the ears, general distress, a sense of apprehension, palpitation, precordial pain, excessive ventricular rate, orthopnea, sweating, toxic erythema and urticaria all took place. Manifestly, therefore, a fairly high percentage of patients presented symptoms which more or less contra-indicate the drug. Out of this number of 286, eight died suddenly, embolus occurring in seven of the eight. In the remaining case the death was apparently due to another cause.

Hay asks the questions, after giving details of other patients who had very disagreeable symptoms: how far are patients benefited by the resumption of normal rhythm? And in which particular type of case should quinidine be exhibited? Or, in other words, when is it worth while? The reply to these questions is that it is most likely to be of service when the fibrillation is of recent development and when there is but little cardiac enlargement and no valvular disease. Again, it does best in a patient in whom the onset of fibrillation was due to some acute infection, as influenza. "Each case must be considered on its merits; often the results are far better and more permanent than was to be expected. More frequently, however, they are disappointing."

The conditions which are unsuitable for quinidine, or in which but little good can be expected to result, are the presence of marked myocardial degeneration with old valvular lesions, and particularly if there is complete failure of compensation with venous engorgement. Here digitalis is the best drug. He also thinks that occasionally in a patient who has suffered severely from angina pectoris followed by fibrillation, quinidine may restore normal rhythm. Idiosyncrasy to the drug may induce unpleasant or even dangerous consequences.

Very definite contra-indications are old cases of acute or sub-acute infective endocarditis, or a history of embolism having occurred in some part of the body. It does not, therefore, follow that because quinidine restores a normal rhythm the patient is going to materially improve. The consciousness of irregularity may disappear, but the actual progress of the patient may not be any more favourable.

To summarize the matter, therefore, the average physician, we think, should never employ quinidine off-

hand; he should use it with great caution as to his early doses, and certainly in the majority of instances should not employ it unless the patient is under absolute control and there is an opportunity before and after it is tried to determine the cardiac condition by use of the electrocardiograph.

Whether resort be had to full doses of digitalis or quinidine, an essential part of the treatment is rest in bed.

"Peracrina" in Malaria.

We have received several notices dealing with a new drug, "Peracrina," in the treatment of malaria.

Dr. J. Walker writes at length of this drug in the *Archives fur Schiffs und Tropen-Hygen.*, 1924, pp. 540 to 570. Some of the temperature charts therein shewn, however, might well be employed to shew the natural course of untreated malaria, as irregular fever with parasites continuing in peripheral blood films for several weeks, in spite of the treatment. In several others "Peracrina" had no obvious effect, whereas quinine caused a prompt fall in the temperature and the disappearance of the parasites.

It is somewhat surprising that great claims are made for the drug in the face of so strong evidence of its inefficiency.

"Peracrina, 303" is said to be a combination of egg-albumin and trypaflavin.

Reviews.

TEXT-BOOK OF PATHOLOGY.—By Robert Muir, M.D., F.R.S., Professor of Pathology, University of Glasgow. Edward Arnold & Co., London, 1924. Pp. 774. Illustrations 433. Price 35s. net.

THIS book is written on the orthodox lines which are followed by almost all writers of text-books of pathology. It is likely to be adopted as a standard text-book for students as it satisfies the needs of examining bodies more completely than any work that we know. It attains to a very high degree of excellence in the illustrations, text and general get up.

It is not the students' text-book of pathology of our dreams; this would present a far smaller amount of information to the student, and from the orthodox point of view would be very incomplete. Only after such an elementary book had been mastered would we allow the student to tackle so complete and systematic an account of pathology as is presented by Dr. Muir.

The medical student of to-day has to learn so much that his brain becomes highly specialised in the assimilation of information, with the result that his powers of observation and his judgment suffer. The process of addition to the knowledge that is required of the student is ruthlessly continued, but the human brain does not increase in efficiency in a proportional degree. In our opinion the present text-book is far too complete, but we predict that its high standard of excellence will result in its wide-spread adoption.

No harm would be done if only a modern Huxley would arise who would give the student a picture of pathology painted with a few bold strokes and leaving the details to be filled in after the broad outlines had been mastered.

Our criticism of the book in short is that it is a complete and thorough exposition of the subject of pathology for the average student.

The book deals with the material which is usually classified as general and special pathology; such subjects as bacteriology, parasitology, diseases of the skin and special senses are rightly excluded as they are invariably included in the text-books on these subjects.

Dr. Muir's book is certain to attain to a great degree of popularity.

HANDBOOK OF BACTERIOLOGY.—By J. W. Bigger, M.D. (Dublin), F.R.C.P.I., D.P.H., Professor of Bacteriology, University of Dublin. London: Bailliere, Tindall & Cox, 1925. Pp. xv plus 413, with 5 colour plates and 66 figures. Price 12s. 6d. net.

THIS is a small book, designed for students and practitioners of medicine and dedicated to the memory of A. C. O'Sullivan, Professor of Pathology, University of Dublin, who died on February 18th, 1924, as a result of an infection of the hand contracted when demonstrating post-mortem specimens to a class.

The author, as a teacher of experience, has realised the formidability of the medical curriculum, in which the ground to be covered in each subject has been increasing by leaps and bounds. He has accordingly endeavoured to compress within the limits imposed by the factors of time and receptivity the essentials of bacteriology requisite for students of medicine.

The chapters dealing with technique, general and special, have been stripped of diffuse details and yet remain quite adequate.

The descriptions of the various micro-organisms are concise and convey plenty of information for those for whom the book is intended. It is of interest to note at the heads of the several chapters the names of the discoverers of bacteria and the dates of their findings.

In the opinion of the reviewer, it would have been a slight improvement to have headed the paragraphs in the chapters with numbers and indications of their subjects in heavy print as such are aids of considerable value to students.

From the point of view of students of medicine in tropical countries, such a book to which have been added sections dealing with the common animal parasites pathogenic for man would be of much value.

In so far as the author's explanation of its publication is concerned, its appearance is amply justified.

THE CIRCULATORY DISTURBANCES OF THE EXTREMITIES, INCLUDING GANGRENE, VASOMOTOR AND TROPHIC DISORDERS.—By Leo Buerger, M.A., M.D., New York City... 192 Illustrations, five in colours. Published by W. B. Saunders Company, Philadelphia and London, 1924. Pp. 628. Price 42s. net.

THIS book deals almost entirely with those circulatory disturbances which may lead to gangrene of part of a limb. The opening chapters describe the anatomy and physiology of the peripheral circulation and more particularly the functions of the vaso-motor mechanism.

Trophic disorders of the skin are dealt with very briefly and then thrombosis and the various forms of gangrene.

A lengthy description of thrombo-angitis obliterans occupies the next 172 pages. The author is a recognised authority on this rather rare disease and it is due to him that the modern name has entirely superseded the older arteritis obliterans.

Needless to say the subject is described fully in all its aspects, and indeed the whole book seems to be built around a discussion of this disease. Arterio-sclerosis, syphilitic disease of the vessels and the various forms of neurotrophic disorders form the remainder of the book, and in the last chapter we find an excellent description of capillary microscopy and its importance as a diagnostic method. There are 192 excellent illustrations. The book should prove valuable as a work of reference, for there is much in it that will not be found elsewhere.

OPERATIVE SURGERY.—By Warren Stone Blackham, M.D. & Phar. M. (Tulane), M.D. (Columbia), F.A.C.S., formerly Surgeon, Manhattan State Hospital, New York and Instructor in Operative Surgery, College of Physicians and Surgeons, Columbia University, etc. In Six Volumes. Philadelphia & London: W. B. Saunders Co. Vol. III., pp. 1001. Illustrations 1250. Vol. IV, 1924, pp. 842. Illustrations 773. Price 50s. net each.

IN our notice of the first two volumes of this work we commented on its general plan and scope, which limits it entirely to a description of operative technique and disarms criticism of omissions by the statement that only the common operations are dealt with. In our opinion the author would have done better to have given us the benefit of his own personal experience, instead of compiling an encyclopædia of all the methods which have been described and used, many of them of historical interest only. As a work of reference, however, the book is very complete, and though the surgeon will have to make his choice in the light of his own experience, he will rarely fail to find a clear and excellently illustrated account of the available operations. Vol. III deals with operations upon the eye, ear, nose and throat, the upper air passages, neck, thyroid and thymus glands, tongue, breast, thoracic wall and lungs. The wisdom of including such special branches as eye and nose operations in a work on general surgery may well be doubted. There are important omissions in some sections, for instance the technique of skin-grafting the cavity left after operation for chronic mastoid suppuration is not described. The surgeon in search of methods of plastic repair for nasal defects will, however, find no less than 53 operations for partial rhinoplasty described and 18 for total rhinoplasty, from which to take his choice. Each of these descriptions is accompanied by a clear illustration, showing the requisite incisions; we know of no other work so complete, and it would be hard to imagine a nasal defect for which a method of repair could not here be found.

We even find a brief section on the extraction of teeth, in which, in a work hailing from across the Atlantic, we were surprised to find no mention of the method of "surgical" removal of the tooth along with the diseased alveolar process, which has been worked out in the Mayo Clinic. Brophy's method of dealing with a complete cleft of the hard and soft palates by approximation of the superior maxilla and fixation with silver wire sutures is accorded the first place in the list of operations for this condition, a preference which this operation has never obtained in Europe.

The section on the thyroid is one of the best in the book, the descriptions of the operations are very detailed, and the author departs from his usual custom and gives us some illuminating comments on the applicability of the various methods of excision and resection: we wish he would do so more often.

The sections on thoracic surgery contain an excellent account of the brilliant work of Lilienthal on chronic empyema, but we were surprised to note the omission of such useful procedures as Chevrier's operation for acute empyema and Wilms' and Sauerbruch's operations for chronic tuberculous empyema. The use of positive and negative pressure cabinets for thoracic surgery has now surely disappeared with the arrival of intratracheal anaesthesia.

In Vol. IV, the subject of thoracic surgery is completed and we enter upon abdominal surgery. The sections on hernia are very disappointing, the John Hopkins method of radical cure of inguinal hernia, the use of fascial transplants in dealing with large herniae, Dujarier's operation for femoral hernia, by opening the inguinal canal and pulling up the sac, and Roux's operation should be described in a work of this size, along with the older operations which are given. Amongst the many methods of suturing the abdominal wall which are illustrated, we find no reference to the use of deep supporting sutures penetrating all layers except the

MAY, 1925.]

peritoneum, which most surgeons employ in addition to the sutures in the various tiers.

The sections dealing with operations on the gastrointestinal canal and with the liver, gall-bladder and bile ducts are exceptionally good and complete, and it is a pleasure to find the author departing so far from his usual rule as to give us a balanced and temperate discussion on the indications for cholecystectomy. The reader will find here recorded all manner of ingenious operations for short circuiting the obstructed bile channels in malignant disease and injury cases, such as he will not find in any other book. It is disappointing to find the use of Murphy's button and other artificial aids to intestinal anastomosis described in detail, as though they were still in use. So, too, with such operations as gastroplication and gastropexy, which are now matters of history for most surgeons. However it is easy to find omissions where the field covered is so vast; and it is pleasant to be able to add that these detract but slightly from the value of a work in which successive volumes continue to maintain the same high standard of excellence.

AIDS TO SURGERY.—By Joseph Cunnings, M.B., B.S., F.R.C.S. (Eng.); and C. A. Joll, M.S. (Lond.), F.R.C.S. (Eng.). 5th edition. London: Baillière, Tindall & Cox, 1924. Pp. viii plus 434. Price 4s. 6d. net.

THIS is the fifth edition of this excellent little work and this alone is sufficient proof of its usefulness and popularity. The recent edition rests entirely in the hands of Mr. Cecil A. Joll.

The book comprises a resumé of the whole of general surgery; it is clearly and simply written.

It will serve as an extremely useful source of information for students preparing for examination.

We cordially recommend it, and feel sure that its popularity will be further enhanced.

RATS AND HOW TO DESTROY THEM.—By Mark Howell, F.R.C.S. London: John Bale, Sons and Danielsson, Ltd., 1924. Pp. xiii plus 465. Price 10s. 6d. net.

AN important book designed to rouse the public from its apathy with regard to rats. The great economic loss due to these creatures is stressed and a tally given of diseases in man and animals caused, possibly caused or not caused by the rodent; in this regard it is not generally known that the exaltation of virulence of some of the so-called rat-viruses in the market has seemed to suffice for the affection of man as well as of the rat, while other pathologists recounted are Weil's disease, rat-bite fever, favus, some of the dysenteries, ringworm, distemper, foot-and-mouth disease, horse-influenza, mange, tapeworm, cancer [per (1) tapeworms and (2) cockroaches and *Gongyloloma*]. The reviewer however dissents from the author's view of the danger of plague in England: the proof of the pudding has been in the eating and the sporadic nature of the outbreaks there for many generations should have reassured the alarmists;—it surely cannot be contended that the health authorities have brought about this happy result. It has been due only to the displacement of the black rat by the brown rat, and the custom of planting hedgerows, which originated about the time of the Great Plague owing to the scarcity of farm labour. The brown rat, unlike the black, disperses widely over the countryside, during the summer months burrowing in the hedgerows; then only would the rat-flea rate be high enough to produce an epizootic of plague, but no serious results follow because of the wide distribution of the rats. At the onset of winter when the creatures return to their association with man, their flea-rate and other conditions are not suitable to produce an epidemic. Thus it has been shewn that the minor outbreaks of the disease in East Anglia have never become serious and never will be.

The book seems to have been designed to encourage private endeavour,—for those whose recreations are "the normal forms of loafing and dilettantism," country squires, clergymen, poachers,—rather than for the public services: thus there are excellent chapters on dogs and sparrow destruction. Nevertheless what appears to be an admirable organisation for county services is suggested to deal with the problem. Insistence is laid on the necessity of a knowledge of the habits of the rat, of which there is a very good account; while among the methods of ratting discussed mongooses are ruled out, the Rodier system is dismissed as at least impracticable, and the employment of viruses strongly objected to on account of their danger to man.

In spite of the all-round excellence of the book for European conditions, it cannot be entirely recommended for India. Its very appeal to self-help rather than for a Government organisation deprives it of nearly all value to this country. The reviewer could tell of fifteen Indian municipalities which, rather than spend per mensem Rs. 2 per persons 300, refused the offer of a Government organisation and the loan free of charge of a very valuable equipment. (Nemesis came to them the year after.) Rat destruction in India must remain a Government perquisite, and the organisation must be quite a different affair to that designed by the author.

As for the technique suitable for India, Kunhardt and Chitré's valuable work in Poona on rats and how to destroy them has been completely ignored. Their conclusions—based on careful experiments—must take precedence over the author's based on experience, and their incorporation into his book would make it even more valuable.

AN INTERPRETATION OF ANCIENT HINDU MEDICINE.—By Chandra Chakrabarty. Published by Ramchandra Chakrabarty: Calcutta, 1923. Price Rs. 7-8-0. Pp. 599.

THIS book consists of nine sections dealing with anatomy, physiology, pathology, diseases and their diagnosis, diseases and their clinical studies, therapeutics, surgery, dietetics and hygiene, with several sub-sections. The book will be of interest as it deals with the ancient Hindu medicine and western medicine side by side in an elementary way, with the exception of certain chapters which deal only with western medicine. There is no sharp line of demarcation between the two systems in the book and in some places the reader is surprised to find descriptions of indigenous medicines side by side with references to the protozoal organisms of malaria, and dissertations on immunity and the principles of vaccine therapy. It will be interesting to follow the progress of those who believe that scientific modern medicine can be combined with the teachings of the ancient systems. We confess that we cannot see any prospect of a useful harmony being produced. It is only in India that such an attempt has been made, and the process suggests the old saying about "running with the hare and hunting with the hounds." Evidently there are some medical men in India who are so optimistic that they believe in the possibility of doing both things at the same time.

COLLECTED PAPERS OF THE MAYO CLINIC AND THE MAYO FOUNDATION.—By Mrs. M. H. Mellish. Volume xv, papers of 1923, published June, 1924. 1377 pages with 410 illustrations. London and Philadelphia: W. B. Saunders Co., Ltd. Price 63s. net.

THIS constitutes a remarkable record of the work of the numerous specialists belonging to the Mayo Clinic and the Mayo Foundation during the year 1923. There are references to no less than 308 papers by 148 authors, but in the case of 97 of the papers the titles only are given and others are abstracted, so that it has been possible to include a record of a vast amount of work. The subjects are grouped under special headings, viz., alimentary tract, urogenital organs, ductless glands,

circulatory system, head, trunk and extremities, and miscellaneous.

Dr. William Mayo in his chapter on the splenomegalies deals with the subject from a broad point of view, taking the spleen to be a portion of the reticulo-endothelial system. "The spleen is the most unstable part of this system, and as such undergoes most marked pathologic changes from causes not arising within itself, but resulting from disturbances in other organs, and when once morbid processes are set in action, they tend to become chronic, progress slowly to a terminal condition which is little affected by treatment." This is true only of splenomegalies not due to known protozoal diseases, such as malaria or kala-azar. Surgical treatment is applicable only to the other types of cases. In the chapter on the internist's responsibility in surgical cases certain important factors with regard to the patients have been considered. In the paper on "The Pathologists of the Twentieth Century" the real status of the pathologist in the profession has been dealt with; the author urges a broad outlook and closer approach to the patient. The book is a mine of information and will be very useful for all medical men who are interested in recent developments of medical and surgical work.

DISLOCATIONS AND JOINT-FRACTURES.—By **Frederic J. Cotton, A.M., M.D., F.A.C.S.** Second edition. Philadelphia and London: **W. B. Saunders Co., 1924.** Pp. 745. Illustrations 1393. Price 50s. net.

THIS is the second edition of this excellent book and its appearance shows the appreciation it deserves as a standard work on fractures and dislocations.

The book has been brought up to date and new chapters will be found dealing with methods which have emanated from the writer's vast experience gained in the surgery of the great war, as for instance, the fixation of infected compound fractures, disinfection and closure of joints and the use of physiotherapy methods.

The book is well written and profusely illustrated by radiograms and drawings, mostly of cases of which the author has had personal experience. Every type of fracture and dislocation is discussed in detail as regards their causation, diagnosis, treatment, after-treatment and prognosis.

A special chapter is devoted to technique, splints and plaster work, which however, might have been discussed in more detail and better illustrated; but, as the author wisely says, of technique one can learn or teach little in a book, as each fracture is a mechanical problem in itself and cannot be treated by routine methods.

We strongly recommend this work to practitioners as a book of reference in their library, to acquaint them with the types of fractures and dislocations that commonly occur; how to carry out the methods of reduction and the application of apparatus that has proved of value; and to outline after-treatment and prognosis.

FACIAL SURGERY.—By **H. P. Pickerill, C.B.E., M.D., M.S.,** late Surgeon in charge of the New Zealand Section, Queen Mary's Hospital, Sidcup. With an introduction by **Sir W. Arbuthnot Lane, Bart., C.B., M.S.** Edinburgh: **E. & S. Livingstone, 1924.** Pp. 162. Price 21s. net.

IN no department of surgery were greater advances made during the war than in the repair of severe facial injuries with loss of tissue. In the early stages of the war these cases were supplied with painted metal masks to fill in the missing portions of the face, a method which was not comfortable for the patient and which involved frequent renewals of the painting, which could only be done by a skilled artist. Thanks mainly to the work done at Queen Mary's Hospital, Sidcup, it became possible to restore almost all such cases by purely surgical means and from the patient's own tissues, an advantage to the sufferer from every point of view. It was obvious that these methods would find a large field of

utility in civilian surgery in the treatment of new growths of the face, lupus, nævi, burns, and congenital and acquired deformities.

In Part I the author, who was in charge of one of the sections at Queen Mary's Hospital, sets forth a brief outline of his technique. The use of pressure skin grafts, epithelial inlays, bone grafts and tube flaps and grafts are described in sufficient detail. The use of the "tube" method of transferring skin from the neck and chest or from the scalp to the face has entirely superseded the old methods described in text-books of cutting flaps from one part of the face to remedy defects in other parts. The latter methods caused much tension and resulted—if successful—in poor mobility of the part, whereas the new methods cause no tension and furnish a perfect functional result. It is to this improvement more than any other that the marvellous results obtained at Sidcup are to be ascribed.

Part II deals with the use of these methods in military surgery. The nose, lips, eyelids, chin, etc., are dealt with seriatim and the author's methods of dealing with each region are described and illustrated by some remarkable photographs.

In Part III, the application of these principles in civil practice is taken up, and this is naturally the most interesting section of the book at the present time. The illustrations of cases show large areas of the face excised for epithelioma or rodent ulcer and replaced by grafts so neatly that hardly any scarring is visible in the photographs. Rhinoplasty is familiar enough in India, but we have never seen such good results obtained as are shown here from the use of tube grafts combined with cartilage grafts; extensive burns would appear also to offer a tempting field to judge from figs. 195 to 198, where a mass of cicatricial tissue binding the chin to the sternum and preventing the patient closing his mouth was replaced by a scalp flap, which supplied a hair-bearing chin and enabled the patient to open and close his mouth.

The author has applied his methods to the treatment of hare-lip and cleft palate with results which appear to be superior to those obtained by the usual methods.

The book is most interesting and valuable to surgeons. It is the first presentation of the subject in a handy form which we have seen, and we commend it to surgeons in India, where we feel that there is a wide field of usefulness for these methods.

THE HUMAN TESTIS AND ITS DISEASES.—By **Max Thorek, M.D.,** Surgeon in Chief, American Hospital; Consulting Surgeon, Cook County Hospital, Chicago, Ill.; President, International Congress of Comparative Pathology, Rome. London: **J. B. Lippincott Company, 1924.** Pp. 548 with 308 illustrations. Price 38s. net.

THIS is an admirable work on the diseases of the human testis by a clinician whose research work is carefully reviewed in the light of clinical findings.

The ordinary diseases of the testis are adequately described, but the main theme of the book is in the domain of the endocrinology of the male gonad with special reference to testicular transplantation in the human subject. As the result of a very interesting series of experiments, the author comes to the conclusion that "the Leydig's cells are alone responsible for the production of the internal secretion that gives rise to the secondary sex characters, sexual potency and cerebral-eroticising products."

The similarity between the bloods of man and the higher anthropoids, together with hetero-transplants of testis from anthropoids to man and vice versa enabled the author to postulate his dictum that "the practicability of therapeutic transplantation from the higher apes to man is proven beyond any doubt." This contention is proved by the fact that the graft, when removed months after the transplantation, is visible, vascularised, shews but little diminution in size, and when sectioned and stained the Leydig's cells are practically normal.

Although it is conceded that the human testis is best for transplants, this source of supply is strictly limited, and the fact that the testes of the higher apes can be successfully utilised marks a distinct advance in the scope of this therapy.

Dr. Thorek in his transplantation technique uses the whole testis and epididymis, whether human or anthropoid, exposes the tunica vasculosa by small punctures with an electric cautery, and places the graft into the peri-renal region of the recipient, having previously made a bed for it in this situation and secured hæmorrhage; he concludes by uniting the muscular layers and skin with sutures.

Sepsis is rarely encountered, and persistence of the graft is the rule. A special chapter is devoted to the indications and contra-indications for sex gland transplantation in the male.

The case reports of his own cases and those of others bear eloquent testimony to the undoubted value of this method of therapy in specially selected cases.

Interesting chapters are those which describe the dystrophies, dementia præcox, and the inter-relation of the glands of internal secretion. Dr. Thorek quotes fully the work of Voronoff, Steinach, Lydston and other workers in this field. The book is well printed in large type, well bound, and excellently illustrated.

DEVELOPMENTAL ANATOMY; A TEXT-BOOK AND LABORATORY MANUAL OF EMBRYOLOGY.—By Leslie Brainerd Arey, Professor of Anatomy at the North Western University Medical School, Chicago. London and Philadelphia: W. B. Saunders Co., Ltd., 1924. Pp. 433 with 419 illustrations, many in colours. Price 27s. 6d. net.

THE modern medical courses demand, rightly enough, a wide knowledge of human embryology, and with a view to meet this demand, Professor Arey has written this extremely useful and practical treatise. The clear and lucid manner in which he has narrated the whole developmental story will, we are sure, make the book interesting reading to those for whom it is intended.

Although fundamentally based on the old Prentiss-Arey text-book, it is essentially new in plan and has been entirely re-written. The various stages in the development have been very clearly and concisely stated, and the book accurately records our knowledge to date on the subject. It contains three sections: the first deals with a comparative study of the early stages of development, both pre-natal and post-natal; the second outlines the origin and differentiation of all the human organs, grouped according to their germ layer derivations; the third section is a laboratory manual for the study of chick and pig embryos, and will be very useful to those who are interested in practical embryology.

We can recommend this excellent manual to medical practitioners as well as to medical students as a sound and complete exposition of the subject.

PHYSIO-THERAPY IN GENERAL PRACTICE AND FOR THE USE OF MASSEUSES.—By E. Bellis Clayton, M.B., B.Ch. (Cantab.), Director of the Physio-Therapeutic Department, King's College Hospital. London: Baillière, Tindall & Cox, 1924. Pp. 174 with 22 plates and figs. Price 10s. 6d. net.

THIS little book is evidently intended for the use of masseuses and gymnastic instructors rather than medical practitioners. The descriptions of the lesions to be treated are worded in simple language, comparatively free from technical terms. After a too-brief introduction on the nature of the treatment dealt with, which might in our opinion be usefully extended to include descriptions and diagrams of the apparatus, electrical and gymnastic, which is used, the author proceeds to give directions for the treatment of most of the common injuries and medical conditions which are likely to be sent for physical treatment. The descriptions of the exercises are brief and clear but their value would, we

think, be much enhanced by a few more illustrations showing the movements in dotted lines. The book will be very useful to those for whom it is intended.

THE EXAMINATION OF WATER AND WATER SUPPLIES.—By J. C. Thresh, D.Sc., M.D., D.P.H., and J. F. Beale, B.A., M.R.C.S., L.R.C.P., D.P.H. London: J. and A. Churchill. 59 illustrations. Third edition, 1925. Pp. 590. Price 25s. net.

THRESH'S "Examination of Water and Water Supplies" has been a standard work of reference for many years to practically every water analyst who can read English. It is no mere compilation of methods. Every description and method of analysis given has been thoroughly tried before adoption, and only those which have proved reliable and trustworthy are included, with such details of description that there is no doubt as to the procedure recommended. The new edition is on the same lines and will be welcomed, not only by analysts but by every one interested in public water supplies. Public water supplies are discussed in all their aspects—the geological source, the examination of the sources, the chemical composition, analyses and their interpretation, and the methods of purification. And every chapter is garnished with the wisdom of ripe experience and acute observation. Difficulties and puzzles are illustrated and explained, and we imagine that there are few situations of difficulty or doubt in which a water analyst or sanitarian could find himself in which he could not find assistance by turning to this book.

In the matter of chemical analysis, it is perhaps striking that there has been no very great fundamental change in the methods of the sanitary analysis of water. The determinations of hydrogen ion concentration and the electrical conductivity are new, but have not given very much more information of a sanitary nature than the older methods. The chapters on chlorination and the excess lime method bring the information on these subjects up to date. Houston's "Reports to the Metropolitan Water Board" have been drawn on to illustrate chlorination, the excess lime method of treatment, the filtrability of water, etc. The excess lime method would seem applicable to many Indian waters, which are loaded with organic impurities—its ability to remove excess organic matter gives it a great advantage over chlorination alone.

The chapters on bacteriological examination present English opinion on the subject and are based largely on Houston's publications. The methods advised for routine use are the total colony count on agar and gelatine, the quantitative examination for typical colon bacilli and the *B. enteritidis sporogenes*. To determine the presence of *B. coli* glucose-bile-salt broth is used: from positive tubes lactose-bile-salt broth is inoculated, and organisms isolated from this are examined for the production of indol and acid and clot in milk. Organisms giving positive results in these media are considered to be *B. coli* of intestinal origin. It is not thought necessary to differentiate these any further; the practical value is said to be negligible. As regards the vexed question of bacteriological standards we quote the following:—

- "We think it safe to draw the following inferences.—
1. That a water containing less than 100 bacteria capable of growing on gelatine at 20° C. in 3 days, and with comparatively few bacteria capable of growing on agar at 37° C. in 24 hours, and which gives no indication of the presence of the *B. coli* group in 100 c.c. can be considered of the highest degree of bacterial purity.
 2. That a water which contains over 1,000 bacteria capable of growing on gelatine, and say over 100 capable of growing on agar, and which contains the *B. coli* as defined in 5 c.c. or less, is probably contaminated with manurial matter and should not be used for drinking purposes unless a thorough examination of the source has proved that such contamination is impossible."
- Between these extremes the water requires a fuller examination and a careful consideration of the result of

chemical analysis, and of the history of the water and its source before a decided opinion can be expressed with regard to its purity and wholesomeness. Where a public supply usually conforms to the high standard given, even if the *B. coli* is found in 100 c.c. and is absent in 50 c.c. it may be considered satisfactory; if found in a much smaller quality, say in 10 c.c., then further investigation is necessary.

Private supplies from wells rarely reach a high standard, and provided the M.O.H. ascertains that there is no source of sewage contamination near, the water may be passed provided it is free from *B. coli* in 10 c.c. and the total bacteria are under 1,000 per c.c.

"There is a tendency amongst chemists and bacteriologists who examine waters to report unfavourably on any sample which contains the *B. coli* in 100 c.c. and frequently the action causes a great deal of unnecessary alarm. This is said to be Houston's standard, totally regardless of the fact that he has always asserted that this standard is only tentative and is to be controlled by knowledge of local conditions. No doubt Houston is endeavouring to get the London water supply up to this standard of purity, but, because it frequently fails to reach this high standard, he does not alarm the metropolis every time he discovers *B. coli* in 10 c.c. or 1 c.c. of the water supplied. If he did, we should live in a state of continuous alarm."

These extracts put the case fairly clearly. It is a little disappointing to find no mention of work done in India on the subject, but apparently faecal bacilli behave differently under tropical conditions. This is a standard work and the new edition will readily find its place on our shelves and benches beside the old one, though in our opinion the bacteriological sections are not quite up to the very high standard of the other parts.

A. D. S.

DISEASES OF THE EYE.—By G. E. de Schweinitz, M.D., LL.D., Sc.D. Tenth edition. London and Philadelphia: W. B. Saunders Co., 1924. Pp. 865 with 434 illustrations and 7 colour plates. Price 50s. net.

This excellent text-book, now in its 10th edition, has been subjected to a very careful overhaul since the last edition, and the changes—though in many places small and only consisting in the addition or alteration of a few lines—still bring the book well up to date and greatly enhance its value.

The actual size of the book is only increased by a few pages, but 25 new illustrations have been added, and many of the old ones have been re-drawn and very much improved in reproduction.

The paragraphs dealing with inflammatory conditions of the interior of the eye, e.g. iritis and cyclitis, have been largely re-written and re-arranged, and the whole new outlook on the pathology and diagnosis of diseases of the eye, due to the new work done with the slit lamp, pervades the book.

This edition like its predecessors can be strongly recommended to all serious students of ophthalmology.

W. V. C.

THE PROGRESS BOOK. AN ILLUSTRATED REGISTER OF DEVELOPMENT FROM BIRTH TILL COMING OF AGE.—By J. J. Pilley, Ph.D. Specially printed for Mellin's Food, Ltd., Indian Dept. Ninth edition, 1923. London: Leadenhall Press, Ltd. Pp. 144. Price 2s.; white cloth, 3s.; half calf, 4s. 6d. Obtainable at all Messrs. A. H. Wheeler & Co.'s railway bookstalls throughout India.

THIS is one of the new, modern and charming books for the expectant and actual mother, which should be popular in every family. "Baby" when grown up, may regard his or her earlier and infantile history as of little interest, but no mother would subscribe to such a heresy. Yet the maternal point of view is innately right; eugenics is not merely a theory, it is an ambi-

tion on the part of every wise pair of modern parents; and this attractive little handbook should prove very popular among parents who wish to record the progress year by year of their children. Successive sections deal with a weight chart up to the 2nd year; important happenings, amongst which the first tooth and the first step naturally loom large; teething; ailments in infancy; mental, educational and religious progress; and a (large) section for individual peculiarities, take a prominent place. Physical progress year by year, from the age of 6 until that of 21, complete the very attractive volume, together with a large blank section for general notes.

That such a delightful book will please parents of the present day, there can be no doubt; it should make a special appeal to both motherhood and fatherhood; should provide a source of both interest and pride. Whether it will appeal to the youngsters on whose ultimate behalf it is got up, is more open to doubt; when they grow up, perhaps shingling will have gone out of fashion, the fox-trot will have been superseded, and present day modes of travel be out of date. On the other hand, if we are ever to have a system of genuine human eugenics,—under which children are born, not by mere chance but under a system of selective and rational breeding, such as we now apply to domestic animals, but have not as yet had the courage to apply to man,—the value of such records will at once become apparent. To-day they may be of merely family interest; to-morrow the nation may come to depend upon such records. At least no modern mother of to-day will expect to rear her infant, without recording the details of "its" progress year by year in some such delightful and charming publication.

MELA MANUAL FOR BIHAR AND ORISSA.—By Lt.-Col. W. C. Rose, I.M.S., Director of Public Health, Bihar and Orissa. Patna: Superintendent, Government Printing, Bihar and Orissa, 1924. Price 4 annas.

THIS little manual has been prepared with a view to helping local bodies to make suitable sanitary arrangements for the conduct of *melas*. Experience has shewn that the sanitation of *melas* is apt to be neglected, partly because it appears to be nobody's business, partly because it is not known what is required, and it is not realised how very important are such fairs in spreading epidemic diseases, and, above all, cholera. A list of the *melas* and fairs held annually in Bihar and Orissa is followed by a chapter dealing with the responsibilities of the local bodies within whose jurisdiction the *mela* is held. It is advocated that the site of the *mela* should be divided into blocks or sections by wide roads, one block or section being allowed for every 5,000 of the daily population, with one jemadar in charge of each block, and one sanitary inspector in charge of every four blocks. Instructions for the preparation of trench latrines, general conservancy, and slaughtering of animals then follow. The equipment needed is then dealt with, followed by a section on water supplies. For disinfection of wells, infected houses, bedding, clothes, etc., chlorinated lime or bleaching powder is recommended, and detailed instructions given as to how to use them. In four appendices methods of preservation of bleaching powder in the tropics, general methods of simple disinfection, measures for the prevention of epidemic diseases, and the use of kaolin in cholera are dealt with. Colonel Ross' little manual is a mine of useful and very practical instruction, and should be invaluable to all who have to deal with general public health matters.

BACTERIOLOGICAL CHART.—By P. Bannerjee, M.B., 7, Barik Lane, Amherst Street P. O., Calcutta. Second edition. Price 5 annas.

THIS well-executed chart will be found useful by all laboratory workers. The author tabulates in turn for all the commoner bacteria, their morphological appearances, motility or otherwise, optimum temperature for

MAY, 1925.]

growth, viability, aerobic or anaerobic conditions of growth, staining properties, and appearances of growth on agar, potato, broth, gelatine and milk media, together with their fermentative properties to different sugar media. The table is well designed and, if framed and hung up in the laboratory, should be very useful to the laboratory worker for reference.

SRINIVASAN'S MEDICAL DIARY FOR 1925.—Published by V. Srinivasan, 44, Rattan Bazaar Road, Madras. Pp. 368. Price Re. 1.

THIS well-designed and well-bound little volume, which we regret to have received rather late in the year, will be of general usefulness to medical men in India. It contains much miscellaneous information of a practical nature, such as changes in the British Pharmacopœia since 1914, tables of metric, British and Indian weights and measures, a posological table, a list of new and non-official remedies with their chemical constitution, notes on incompatible drugs, on the indigenous names for recognised drugs, general prescriptions, medico-legal information, ophthalmic and dental notes, a very complete "national" calendar in which the dates of the months in English, Tamil, Telugu, Malayalam and Hindustani are given, and finally a diary giving a full page for each day of the year. The volume has obviously been compiled with considerable care, and should prove very useful to the general practitioner.

PERNICIOUS ANÆMIA AND APLASTIC ANÆMIA.—By Arthur Sheard, M.D. John Wright & Sons: Bristol, 1924. Pages 94. Price 7s. net.

THIS small book is a thesis presented for the M.D. degree of Leeds, and after reading it one is not surprised to learn that the degree with distinction was awarded.

The brief historical resumé of the subject is the best we have seen, it includes in six pages all the outstanding features of the story of pernicious anæmia. Then follows an account of fifteen cases which were studied in detail and a discussion of the causation of the disease. The author concludes that the disease is really a clinical entity which occurs in persons who have already had achlorhydria. The essential causative factor is a gastrointestinal infection whose nature is as yet unknown.

The treatment which is recommended consists in careful search for any focus of infection, especially in the region of the teeth. Arsenic is recommended, also the administration of a drink containing increasing amounts of hydrochloric acid. Blood transfusion and splenectomy are measures which are regarded as being worthy of consideration, but the author is by no means unduly optimistic as to their value.

Aplastic anæmia is regarded as a pathological syndrome rather than a disease; it is characterised by a serious diminution of the blood-forming function of the bone marrow, whereas in pernicious anæmia there is hyperplasia. The causes are either over-stimulation of the bone marrow with subsequent exhaustion, or primary inhibition of the blood-forming function of the bone marrow. Some of the ætiological factors are severe hæmorrhagic infections, trinitrotoluene poisoning, x-rays and arsenic.

There is no evidence of blood destruction in most cases, nor is there any attempt at blood regeneration, such as is seen in pernicious anæmia.

Although the thesis does not shed much light on the essential causation of these two grave forms of anæmia, it forms a valuable addition to the literature of the subject, and the observations of the cases which are recorded are models of completeness.

A MANUAL OF MEDICINE.—By Dr. T. K. Monro, M.A., M.D., Professor of Medicine, Glasgow University. Fifth edition. London: Baillière, Tindall & Cox, 1925. Pp. xviii plus 1033. Figs. 55. Price 25s. net.

THIS excellent and well balanced text-book has gone through five editions and one reprint since 1903. The

present edition has been thoroughly revised and new articles are numerous, for example such diseases as lethargica encephalitis, tularæmia and cœliac disease are described, and recent work on blood sugar and cardiology is dealt with.

A due proportion is maintained between the descriptions of the various diseases, those of minor frequency and importance are briefly described while fuller treatment is given to the great diseases which form the major part of the physician's work.

In the descriptions of the diseases of temperate climates there is little to criticise and the student and practitioner will find the book a thoroughly reliable guide. In some of the tropical diseases certain errors have crept in, for example, epidemic dropsy and famine dropsy are confused, so are the Japanese seven days' fever and the seven days' fever of Indian ports. Such mistakes are excusable as they are also found in standard text-books on tropical diseases, and it is likely that they will continue to be repeated in text-books on medicine for years to come.

The section on diseases of the nervous system is particularly good and the student who employs this book will find that his path through the mazes of this difficult subject is greatly simplified. In spite of the inclusion of modern methods of diagnosis and treatment, the author has successfully steered clear of the temptation to discard the older and simpler methods which have stood the test of time and which are in many cases most suitable for the general practitioner. There are quite as many temperature charts as it is customary to include in such text-books, and when we complain of the fewness of these we are not criticising this work except in common with the others of its class.

Monro's book will doubtless continue to be a popular and helpful text-book for years to come.

ANNUAL REPORTS.

ANNUAL REPORT ON THE HOSPITALS AND DISPENSARIES IN THE CENTRAL INDIA AGENCY FOR THE YEAR 1922, AND ON VACCINATION FOR 1922-23. BY LIEUT.-COLONEL W. R. BATTYE, D.S.O., I.M.S. CALCUTTA: SUPD'T. GOVT. PRINTING, INDIA, 1924. PRICE RS. 2-12-0.

THE total number of hospitals and dispensaries in Central India during the year was 215 as compared with 224 in the previous year. In 1921 nine dispensaries were closed by the Bhopal Darbar, and in 1922-23 three new ones were opened in Rewa State. There were improvements in the buildings at the King Edward Hospital, Indore, the Sehore Agency Hospital, and the Dewas Senior Branch Hospital. In all 1,579,456 patients were treated during the year, including 20,826 in-patients. The chief diseases treated—in order of prevalence—were malaria, eye diseases, skin diseases, disorders of the digestive system, ulcers and rheumatic affections. Admissions for both syphilis and tuberculosis showed a marked increase on those for the previous year. The King Edward Hospital, Indore, is doing splendid work, but is severely hampered by want of funds in all its activities. The Indore State Medical Department continued to make good progress, especially in its electrical and radium department and in clinical laboratory work.

There were 372 qualified medical men and women in Central India during the year; viz., 5 I.M.S. officers, 225 graduates of Indian universities, 1 male mission doctor, 119 sub-assistant surgeons, 13 private practitioners, 4 lady doctors of missions, and 5 Indian lady graduates. Also 89 senior compounders who held charge of smaller dispensaries. The total sum expended by the Durbars on medical institutions during the year was Rs. 7,11,995, and that from Imperial revenues

Rs. 1,30,296. The former represents a proportion varying from 1.1 to 5 per cent. of the total revenue for different States.

Turning to vital statistics for the year, the registration is admittedly inaccurate and the actually recorded birth-rate is only 8.05 per mille. The variation in neighbouring States however varies from 10 to 18 per cent. and it is obvious that this figure is quite untrustworthy. The total number of deaths has fallen from 238,494 in 1919 during the influenza pandemic, to 58,914 in 1921, and 51,032 in 1922.

Vaccinations numbered 146,396 in all, and 188 vaccinators were employed during the year 1922-23.

The Central India Agency was free from cholera during 1922, but plague was of rather severe type and caused 1,019 attacks with 747 deaths. Rewa State and Bundelkhand suffered most severely, whilst the disease appeared in Nowgong Cantonment for the first time. It was prevalent both from February to April and from September to December. Small-pox was unimportant during the year, but influenza caused some anxiety in Indore, Bundelkhand and Baghelkhand; a total of 2,448 cases with 100 deaths is reported.

There is only one lunatic asylum in Central India,—that in Indore city, with accommodation for 12 patients. Colonel Battye reports that "this building is not fit for the accommodation of human beings." During the year Her Highness the Maharani Chandrawati-Bai very kindly offered a large building at Banganga for this purpose, but—owing to the usual lack of funds—it could not be utilised. Lepers are accommodated in four asylums, at Indore city, Barwani, Sehore and Dhar,—the second a new institute, and the fourth run by missionary enterprise.

Returns are recorded from 33 jails and lock-ups for the year. Their death-rates shew most extraordinary variations, from 14.9 per mille for Indore State central jail to 107.9 per mille for Rewa central jail. The latter indeed reported a death-rate of 158 per mille in 1921. At Nowgong district jail under the Imperial government the death-rate was 20.6 per mille.

There were 21 pupils trained under the auspices of the Victoria Memorial Scholarship Fund in midwifery and child welfare at the King Edward Hospital, Indore during the year, and 6 at the Bhopal State Hospital. There were 100 students at the Medical School attached to the former institution, on January 1st, 1922, of whom 22 qualified during the year. Admission of new students was temporarily suspended for some months whilst an enquiry was held as to whether funds would permit of further admissions; fortunately the School was re-opened for fresh admissions in July, 1922, and by the end of the year 138 students were attending the School.

REPORT ON THE LUNATIC ASYLUMS IN BURMA FOR THE TRIENNium 1921-23. BY COLONEL P. DEE, I.M.S., INSPECTOR-GENERAL OF CIVIL HOSPITALS, BURMA. RANGOON: SUPDT., GOVT. PRESS. PRICE RE. 1-14-0.

THE two mental hospitals in Burma, at Rangoon and Minbu respectively, continued to function during the triennium. Their total accommodation is for 770 patients, but there has been a marked increase in the numbers admitted, and at the end of 1923 there were no less than 1,155 patients; 992 males and 165 females. Overcrowding at the Rangoon asylum has therefore been the outstanding feature of the triennium, and relief was obtained only by using day sheds and work sheds as sleeping barracks for the excess population. A new asylum is in course of construction at Tagdale, and it is hoped to open this shortly. Even so, however, it is evident that the accommodation provided is far too little for present-day requirements.

General health was good during the triennium, the daily average sick having fallen from 152 in 1921 to

123 in 1923. There was no epidemic disease, but the inmates of the Rangoon asylum were inoculated against plague when this disease was prevalent in Rangoon town. Mortality was 9.74 per cent. of patients in 1923. This rather high figure is due to the admission of new patients in a bad state of health; no less than 12 out of the 66 deaths which occurred were among patients who had been less than six months in the asylums. Tuberculosis, with 24 deaths, heads the list, followed by chronic diarrhoea and dysentery with 15 deaths.

Rangoon itself supplied no less than 56 per cent. of the admissions; and Major Robson, I.M.S. attributes this to the fact that Rangoon is the main artery of flow of the immigrant itinerant labour into and out of Burma. This labour is of very poor type, and liable to both tuberculosis and confusional insanity following upon acute specific diseases. Almost 70 per cent. of the patients were between 20 and 40 years of age.

The chief types of insanity among the cases treated were mania and melancholia; 20 cases of insanity were attributed to the use of *Cannabis indica* and some 50 per cent. of such cases are curable. There was only one escape during the triennium. There was one case of fatal and accidental injury; and one of murderous assault by a patient in the Rangoon asylum on an overseer and two door-keepers. Injury compensations of Rs. 175, Rs. 100 and Rs. 40 were paid to these three individuals.

The main lines of treatment are to keep all new admissions as free from distracting influences as possible, to restore the general health by regular and careful dieting, and to secure the maximal amount of sleep obtainable, assisted as necessary by sedative medication. In minor cases paraldehyde is the great stand-by; for states of excitement and agitation, bromides and chloral are best; finally hyoscine will frequently act in intractable cases where all other agents have failed. Once convalescent, the patient is put on to occupational therapy, gardening, weaving, tailoring, road repairs, cleaning and keeping quarters; males also to paddy grinding, dairy, carpentry, and masonry, females to cleaning paddy. The system of paying monthly stipends to well-behaved inmates at varying rates according to merit is very much appreciated in Rangoon asylum.

Conservancy is good, and the buildings are clean and comfortable. Amusements, including *frées*, and musical and gramophone parties are held periodically. At Rangoon asylum there are annual sports for inmates, and the Rangoon Battalion A.F.I. band plays once a week. Newspapers are permitted to well-conducted patients, and friends and relatives are permitted to visit suitable patients.

The garden and dairy at Rangoon asylum is self-supporting, and is even making money.

Colonel Dee complains with some justice of the casual way in which medical history sheets of newly admitted patients are filled in, information with regard to past history, hereditary influences, etc., being written up as "unknown." Such case sheets are quite useless, but it is difficult to get a committing magistrate to take an interest in such matters as hereditary influences, occupation, etc. Delays and omissions to send in the prescribed documents with criminal lunatics are another source of considerable trouble. Twelve meetings of the Committee of Management of the Rangoon asylum and five of the Minbu asylum were held during the triennium, the latter but poorly attended, 3 members present as a rule out of 10.

Receipts in 1923 amounted to Rs. 3,28,854, the amounts realised from paying patients totalled Rs. 49,558, and the net expenditure was Rs. 2,76,142. Receipts from paying patients shew a steady increase annually. The cost of diets was appreciably reduced, in spite of the marked increase in population to be fed, chiefly by making better and more favourable contract rates. The one and only donation towards the splendid work which these two asylums carried out during the triennium was a

donation of Rs. 100 by His Excellency Sir Harcourt Butler, Governor of Burma.

REPORT OF THE EUROPEAN MENTAL HOSPITAL AT RANCHI FOR THE TRIENNIUM 1921-23. BY MAJOR O. A. R. BERKELEY-HILL, M.D., I.M.S. PATNA: SUPERINTENDENT, GOVERNMENT PRINTING, BIHAR AND ORISSA, 1924.

MAJOR BERKELEY-HILL's annual reports are always interesting reading, and this one is no exception to the rule. During the triennium, the Ranchi "asylum" became a "mental hospital," and the former "blocks" became wards, at least in name. Female attendants have replaced the former male attendants in the male section, with the exception of one European male attendant who has been retained in order to run the brass band and the patients' outdoor games. This change has been all to the good, and there has been a marked improvement in the general condition of the male patients, even of the worst cases; patients who had been addicted to walking about exposed have taken to clothing themselves and behaving properly, whilst those with a tendency to violent behaviour have "invariably responded to feminine influence." Wards are no longer untidy, and meals are punctually and agreeably served. The Local Government have adopted a proposal to abolish the post of European head attendant in the male section, and instead to recruit from Home a matron-in-chief.

The most notable event during the triennium was the constitution of a board of trustees, which took over the entire management and control of the hospital with effect from July, 1922. Another important event was the affiliation of the hospital in 1922 to the University of London in connection with the examination for the diploma in psychological medicine; and Dr. Jyotirmoy Roy, civil assistant surgeon of the Ranchi hospital, is to be congratulated on having taken this diploma after 16 months of study leave in England.

The number of patients accommodated varied from 167 in 1921 to 151 in 1923, admissions averaging 52 per annum. Re-admissions reached a total of 12 during 1923; and Major Berkeley-Hill comments with regard to this on the way in which relatives evade the responsibility of maintaining discharged patients; "in the present state of the law it is not possible to bring pressure to bear on relatives to take charge of cases sufficiently well who no longer need institutional care, except married women whose husbands are bound by law to support them, and children whose care parents cannot refuse or evade." Under the existing laws the "patient" is defined as such from the legal and not from the medical point of view; "in effect the attitude which the law takes to a person suffering from mental disease is that he shall not enter an asylum for care and treatment unless circumstances force it, nor shall he remain there, if it is possible for him to be outside. Nowhere does the law urge upon citizens the duty of taking prompt steps for the proper care and treatment of the mentally afflicted; on the contrary, it treats such steps with suspicion and imposes restrictions, so much so that those primarily concerned, i.e., the patient, his medical attendants and his friends and relatives, avoid invoking the law's aid." In no less than 33 per cent. of the cases admitted during the triennium there had been failure on the part of the committing magistrates to comply with the provisions of the law, and in such cases the medical superintendent is open to a process at law. The demand for reform in the lunacy laws in India, says Major Berkeley-Hill, is very urgent; and he states that matters are nearly as bad in India as in Spain, where a father was so worried about the difficulties of admitting his insane son to an asylum that he committed suicide.

Criminal insanes decreased in number during the triennium from 12 to 3, but there was an increase in

the number of voluntary boarders from 5 to 11. Of 21 such voluntary boarders no less than 18 recovered without being formally committed as patients. The bad old custom of detaining suspected insane persons in jails for observation of their mental state still persists throughout India; and, as every civil surgeon knows, is a "deplorable anachronism." "Were the public aware of the suffering frequently caused thereby to persons afflicted with mental diseases, it is likely that my yet feebly appreciated plea for the institution of a psychopathic ward in every general hospital of any size would become a matter of real significance to the public," writes Major Berkeley-Hill. In one matter, however, he has secured reform; female patients sent for admission are now accompanied by at least one European or Anglo-Indian nurse, instead of only by a police sergeant.

The mean annual population in the hospital during the triennium was 206, of whom 114 came from Bengal, 57 from the United Provinces, and only 14 from Bihar and Orissa. Eleven per cent. of cases are recorded as cured, and 2.4 per cent. as improved. The two months' parole system has worked well, 7 out of 10 such cases on parole having been finally discharged cured at the end of the two months' absence. Committees of visitors have been formed in Calcutta, Lahore and Allahabad to watch and report on patients discharged from the hospital to a home environment which there was good reason to suppose was defective from a mental hygienic standpoint. The reports received by the follow-up letter system have been highly satisfactory in the majority of cases. The Government of Burma have given a lead to all India by incorporating a mental branch in their new Hygiene Institute.

Deaths totalled 7.09 per cent. of the daily average strength, the chief cause being pneumonia. The daily average sick rate was 4.71, as compared with 6.01 in the previous triennium, malaria being the chief cause of sickness. One patient having been assaulted by a member of the inferior staff, the case was referred to the court of the sub-divisional officer, Ranchi, but no conviction followed. It is to be noted that the Indian Lunacy Act of 1912 entirely omits to include any penal clause for dealing with an assault on a patient by a member of the staff of a mental hospital.

The chief forms of mental disorder treated were primary and secondary dementia, 70 cases per annum; dementia praecox, 54 cases; delusional insanity and paranoia, 18 cases; and circular insanity, 11 cases. The hospital obtained the services of a qualified dental surgeon, Dr. Mono Mohan Das, towards the end of 1922; and Major Berkeley-Hill notes how, at the Trenton State Hospital, U. S. A., the introduction of the thorough treatment of oral and dental sepsis was followed by an increase in the average number of monthly discharges from 43 per cent. to 80 per cent. With regard to general therapy, occupational therapy looms large; hydrotherapy is used in an increasing degree; whilst psycho-analytical treatment can now be carried out in the newly completed psychological laboratory. 97 patients were granted local parole, and 30 Ranchi parole during the triennium, with no untoward results. The band played regularly during 1923, and weekly concerts are held; the fund for the purchase of a cinematograph continues to grow; whilst Major Berkeley-Hill has made over his own collection of over 400 books to the institution's library. Twenty-four papers and articles were published by the members of the staff during the year, or read before learned societies. Two "shelters" in the grounds have been converted into aviaries, and two others into work-shops. The average expenditure per annum has risen from Rs. 1,12,958 in the triennium 1918-20, to Rs. 3,59,661 in 1921-23; this may seem objectionable from the point of view of a finance department, but it means a very real and solid advance in the comfort and happiness of the patients concerned.

In the final section of his report, Major Berkeley-Hill deals with problems and difficulties. He considers the appointment of a qualified alienist to the staff, in

addition to the Medical Superintendent, essential; but where is such a person to come from? No military assistant surgeon who has taken a British degree will take up such unremunerative work, whilst it is unlikely that any qualified British alienist would care to work in a place where the facilities for pathological work for example are a disused lavatory, 7 ft. 9 in. by 8 ft. in dimensions, fitted up as a laboratory. There are very few qualified alienists among the junior ranks of the I. M. S., whilst recruitment of British officers to that service now barely fulfils military requirements. Possibly the problem can be solved by the appointment of an alienist "belonging to one of the numerous nations in Europe for whom the conditions of existence have been rendered so intolerable by the Treaty of Versailles that men are willing to take up employment on a very moderate stipend to escape the confines of their own country"; and three such applications have been received, one from a highly trained and well known neurologist and psycho-therapist. Here the difficulty is how to get a medical man with medical degrees taken on the continent of Europe, but not in Great Britain or India, on to the medical register in Bihar and Orissa. Anyone familiar with red tape will realise the seriousness of such a problem, but Major Berkeley-Hill hopes that it is not incapable of solution.

A second difficulty is the nursing problem; "the pay and conditions of service are decidedly good, but mental hospitals are still regarded as God-forsaken places of confinement, and many people still feel that it is a disgrace to be connected with them in any capacity"; in the last 12 months there have been 16 changes in personnel among a nursing personnel of 14. The ideal mental nurse has still to be found; at present she does not exist, even in America, where the same problem has to be faced in the mental hospitals.

If we have devoted space to Major Berkeley-Hill's report, it is because of its great interest. The problems of mental diseases in India—especially among India's European community—present many features different from those in Europe. The subject is as yet an almost untilled field; how little attention it has received may be gathered from the usual and disgraceful practice of detaining such suspected insane persons in jails for observation. The change from regarding asylums as "asylums" to regarding them as "mental hospitals," however, and the introduction of the committee system of management in place of routine government supervision, are both steps in the right direction, and hold promise for the future study of mental disease in India.

Correspondence.

INTRAVENOUS VERSUS INTRAMUSCULAR QUININE.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—Will you permit me to make a few remarks on Dr. R. A. Murphy's letter on "Intramuscular Quinine" appearing on page 48 of your January 1925 issue.

With my own experience to back me, I sturdily answer his question in the last line of paragraph 2 of his letter with a *Yes!* There is no doubt that in cerebral malaria the intravenous route is the only one which makes an early impression, but this must be combined with amyl nitrate inhalation when available (to open up the blocked capillaries) and either adrenalin (1-1000) solution m.x. or $\frac{1}{2}$ c.c. pituitrin to combat collapse. And what about the type known as abdominal malaria, where the splanchnic vessels are similarly charged with malarial organisms? I have seen more than one case of this type labelled acute peritonitis and made ready for the operation table, which yielded almost magically to an intravenous quinine injection in 12 hours or less! This

is more than one can say of quinine by the intramuscular route which I believe takes 4 to 6 hours for its absorption.

Personally, I loathe intramuscular quinine injections whether in the arm or gluteus, and I would never undertake one without the gravest qualms of conscience, and certainly never in private practice! A case of necrosis of the glutei muscles which I saw in hospital practice some 17 years ago made the deepest impression on my then young mind—the case was that of an intensely anæmic Hussar who was the subject of malignant tertian malaria and who had eventually to be invalided from the army on account of a completely destroyed right gluteus which was incapable of being restored to normal bulk. Repeated cultures proved sterile, which rules out any doubt of care and caution in technique. Partly, the huge dose of 20 grains of quinine bihydrochloride given was to blame for the unhappy result.

On the other hand I have given hundreds of intravenous injections and have never met a case that did not live to be photographed, nor have I heard of one. Quinine is an antiseptic of high power and is easily absorbed into the blood when injected into the stream direct. I am convinced that in time the intravenous route will be the *prima via medicatrici* of most medicines and the profession will have then lost their shyness and fear of this method.

One more remark, Sir, before I conclude. In the editor's note to Dr. Murphy's letter it is said that "tetanus spores were present in the distilled water," which, it is concluded, caused death from tetanus in the sad case you relate, with which I am also familiar. The point is whether such spores can produce the disease at all. On page 793 of Dienlaffoy's "Text-book of Medicine," Vol. II, it is claimed that sporular cultures of tetanus from which the living bacilli and tetanus toxins have been removed by heating for 3 hours at 80° C. are harmless in the guinea-pig as long as they are not associated with a culture of the so-called assisting microbes or with a mechanical agent such as lactic acid, producing negative chemiotaxis as regards the phagocytes. It is possible to inoculate guinea-pigs with doses of $\frac{1}{4}$ to $\frac{1}{2}$ c.c. of these cultures, which contain only spores, without the animal presenting symptoms of tetanus. The pure spores do not germinate in healthy tissue and therefore cannot produce the toxin which is indispensable to the development of tetanus.

I am not a bacteriologist, Sir, but when an eminent physician like Dienlaffoy speaks, one must listen. The only point now remaining for elucidation is whether or not the malaria protozoon can correctly be regarded as an assisting microbe to the tetanus bacillus. Personally, for obvious reasons, I think not. I know the theory of the harmlessness of tetanus spores to healthy tissue will stagger the average practitioner, and it certainly set my mind dwelling on the fourth dimension. But is this after all any more wonderful than the residence of diphtheria organisms in the human throat without any active sign of the disease? These are points for the future to settle.—Yours, etc.

B. J. BOUCHE,
Asst. Surgn., I.M.D.

JURONG: SIMLA HILLS,
2nd March, 1925.

[Note.—As shown by Majors Acton and Chopra, intramuscular injections of any of the cinchona alkaloids are followed at the site of injection by focal necrosis of the muscle tissue, whilst if an acid salt be used—as is usually the case—there is, in addition, local hæmorrhage and œdema. Such focal necrosis is a sterile one; but it is capable of providing an anærobic nidus in which any tetanus spores introduced will germinate and cause tetanus. A well known experiment in pathology is that washed tetanus spores when introduced into the muscles of the guinea-pig do not give rise to the disease; but if the site of injection be crushed so as to provide a suitable focal necrosis, the disease ensues. Should septic organisms settle in the nidus, an abscess will result.

The medical practitioner who decides to give intramuscular injections of the cinchona alkaloids should visualise for himself the conditions which will result and decide whether or not the injection should be given.—
EDITOR, I.M.G.]

AN ANTIMONY RASH.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I shall be much obliged if you will kindly publish the following note on a case of kala-azar in your paper. The case appears to be an interesting one and suggests the need for more study and observation on the cases treated by urea stibamine with reference to the particular point concerned.

The patient was a Hindu lady aged 25, with 5 months' undulant fever but with no clinical signs and symptoms of kala-azar and no malaria. Liver puncture showed films negative but N.N.N. culture positive on the 7th day, thus proving kala-azar to be the diagnosis. Urea stibamine was started and given every alternate day, the temperature running from 103 to 105° F. daily. After the 9th injection (1.95 gm.) of urea stibamine the temperature came down to normal. Three more injections were given in decreasing doses at longer intervals, but with each injection a most unbearable and troublesome type of itching was found to commence all over the body immediately after the injection, with the production of a peculiar red eruption like an urticarial rash—(urea stibamine rash, I should call it)—all over the body, lasting only for half an hour. The patient had no trouble in the intervals of treatment. The injections were now discontinued. The patient was seen again four months later and found to be keeping quite good health. No puncture was done to prove cure. The doses given were 0.1 gm., 0.15 gm., 0.2 gm., 0.25 gm., 0.25 gm., 0.25 gm., 0.25 gm., 0.2 gm., 0.2 gm., 0.15 gm., and 0.1 gm., in 2 per cent. solution. The salt was purchased from Messrs. Bathgate & Co., Calcutta, and the patient was treated in Shillong. The idea of publishing this case is to ask medical men whether any of them have noticed such a urea stibamine rash in any of the cases treated by urea stibamine.—Yours, etc.,

SARAT SASI KUNDU, M.B.,
Asst. Surgn., Sylhet.

SYLHET,
5th March, 1925.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel J. M. A. Macmillan, M.D., F.R.C.S., I.M.S., is appointed to be Civil Surgeon, Simla (East), with effect from the date on which he assumes charge from Lieutenant-Colonel Sumner.

Lieutenant-Colonel G. Hutcheson, M.B., I.M.S., is appointed to officiate as Inspector-General of Civil Hospitals, United Provinces, during the absence on leave of Colonel A. W. R. Cochrane, I.M.S.

The services of Lieutenant-Colonel F. W. Sumner, M.D., F.R.C.S.E., I.M.S., Civil Surgeon, Simla (East), are replaced at the disposal of the Government of the United Provinces, with effect from the 25th March 1925.

Lieutenant-Colonel J. Masson, I.M.S., is appointed as civil surgeon of Ranchi, with effect from the 21st November 1924.

Lieutenant-Colonel J. Masson, M.B., F.R.C.S.E., I.M.S., is appointed to officiate as Inspector-General of Civil Hospitals, Bihar and Orissa, with effect from the 13th March 1925.

Lieutenant-Colonel L. Cook, I.M.S., is appointed as civil surgeon of Bhagalpur, with effect from the 17th November 1924.

The services of Lieutenant-Colonel H. G. Stiles-Webb, I.M.S., are placed temporarily at the disposal of the Government of the Central Provinces with effect from the 14th February 1925.

Major A. W. Duncan, I.M.S., officiating civil surgeon of Shahabad, is appointed to act as civil surgeon of Champaran during the absence, on leave, of Major C. G. Howlett, I.M.S., with effect from the 1st April 1925, or any subsequent date from which he may avail himself of it.

The services of Captain G. H. Fraser, I.M.S., are placed temporarily at the disposal of the Government of Bihar and Orissa for employment as Officiating Superintendent, European Mental Hospital, Ranchi, with effect from the date on which he assumes charge of his duties.

Captain C. H. N. Baker, M.C., I.M.S., has been appointed to be Officer-in-Charge, Medical Stores Depot, Rangoon, in addition to his other military duties, with effect from the 3rd December 1924.

Captain A. C. Craighead, M.B., I.M.S., is appointed temporarily to the Medical Research Department and posted as a Supernumerary Officer at the Central Research Institute, Kasauli, with effect from the date he takes over charge.

The services of Captain N. Briggs, I.M.S., are placed temporarily at the disposal of the Government of the Punjab for employment in the Jail Department.

LEAVE.

Colonel A. W. R. Cochrane, M.B., F.R.C.S., I.M.S., Inspector-General of Civil Hospitals, United Provinces, is granted leave on average pay for 3 months with effect from the 8th April 1925 or the subsequent date from which he may avail himself of it.

Colonel J. A. Black, M.B., I.M.S., Inspector-General of Civil Hospitals, C. P., is granted leave on average pay for 5 months and 27 days combined with leave on half average pay for a total period of 8 months with effect from the 13th March 1925, or the subsequent date on which he may avail himself of it.

Colonel H. Ainsworth, M.B., F.R.C.S., I.M.S., Inspector-General of Civil Hospitals, Bihar and Orissa, is granted leave on average pay for five months and twenty-four days and leave on half average pay for the remaining period up to a maximum of eight months leave in all, with effect from the 13th March 1925, or the date on which he avails himself of the leave.

Major G. M. Millar, O.B.E., I.M.S., an Agency Surgeon, is granted combined leave for one year with effect from the 22nd November 1924.

Major O. A. R. Berkeley-Hill, I.M.S., Medical Superintendent of the Ranchi European Mental Hospital is allowed leave for eight months on medical certificate, viz., leave on average pay for six months and twenty-one days and leave on half average pay for the remaining period (including leave not due for nineteen days) with effect from the 6th February 1925, under Fundamental Rules 77, 81 (b) and 81 (c).

PROMOTIONS.

Major to be Lieutenant-Colonel.
W. S. Nealor. Dated 31st January 1925.

Captains to be Majors.
E. Calvert, M.B. Dated 25th July 1924.
R. Sweet, D.S.O., M.B., F. Phelan, N. C. Kapur, N. K. Bal, M.C., H. S. G. Haji, M.C. Dated 25th January 1925.

Lieutenant to be Captain.
R. C. Phelps, M.B. Dated 19th February 1921.
(The seniority of this officer in the rank of Captain dates from 1st November 1916 as notified in the London Gazette, dated 19th January 1923.)

RETIREMENTS.

Subject to His Majesty's approval, Colonel F. Wall, C.M.G., K.H.S., I.M.S., is permitted to retire from the service with effect from the 5th March 1925.

The King has approved the retirement of Lieut.-Col. H. Emslie-Smith, M.B., I.M.S., with effect from the 6th January 1925.

THE MINTO MEDAL FOR RESEARCH WORK IN TROPICAL MEDICINE.

THE Minto Medal of the Calcutta School of Tropical Medicine and Hygiene, which is awarded annually to an Indian worker for distinguished research work in tropical medicine, has been awarded for 1924 to Major R. N. Chopra, M.A. M.D. (Cantab.), I.M.S. Our readers are well aware of the valuable and critical work which Major Chopra has carried out in the field of pharmacology and of investigation into Indian indigenous drugs, and will agree with us in congratulating him on its recognition.

Previous recipients of the medal for the years 1920-1923 have been Lieut.-Colonel R. Row, M.D. (Lond.), D.Sc. (Lond.), O.B.E., I.M.S.; Rai Dr. U. N. Brahmachari Bahadur, M.A., M.D., Ph.D.; Captain K. R. K. Iyengar, M.B., D.P.H., I.M.S., and Dr. D. A. Turkhud, M.B., C.M. (Edin.).

NOTES.

MESSRS. WATSON AND SONS' (ELECTRO-MEDICAL) NEW APPARATUS.

MESSRS. WATSON AND SONS (Electro-Medical), Sunic House, 43, Parker Street, Kingsway, London, W.C. 2, have always been noted for the fineness of their radiographic instruments and for their pioneer work in radiography. Two of their recent bulletins contain accounts of novelties of much interest.

The first deals with the "Sunic Intensifier Screen," the result of three years of experiment and investigation. In order to convert x-rays into rays of greater photographic power and reduce the exposure, calcium tungstate has proved the most satisfactory substance for the screen. Yet there are difficulties; supplies of this compound are often impure, whilst a binder has to be used to hold the minute crystals of the salt together, and yet must be used in such minute quantity that perfect freedom from grain with maximum effectiveness may be obtained. As regards the fineness of grain the Sunic Intensifier Screen is so fine that it is claimed that in high power micro-photography there is only a trifling difference between negatives made with and without the screen. The screen is claimed to be considerably faster than other screens on the market; the utmost care is taken to ensure good contrast and uniformity; whilst the screen is claimed to be so durable that it will withstand nail scratches, can be vigorously washed with a sponge and hot water, or even with a soft nail-brush; whilst it is soft and pliable and can easily be bent or even rolled without danger of cracking the surface. The prices vary from 15s. each of $6\frac{1}{2} \times 4\frac{1}{2}$ in. size, to £3 7s. 6d. for the 15×12 in. size; whilst balanced paired screens are also supplied for double screen technique.

The second brochure deals with the "Sunic" Potter-Bucky Diaphragm. This is a moveable grid, worked by a spring motor, aiming at giving radiographs cleaner, richer in detail and of greater diagnostic value than before. During the making of radiographs, a certain proportion of the rays are scattered by the tissues of the body, and it is the object of the Potter-Bucky Diaphragm to cut out the scattered rays, some 85 or 90 per cent. of which should be cut out if the grid is to be successful in achieving its object. The "Sunic" Potter-Bucky Diaphragm is constructed of alternate strips of wooden and leaden strips, the materials for which are very carefully selected. The wooden strips act as windows, permitting the passage of the rays; the leaden strips as stops, cutting out the scattered rays.

The framework of the apparatus has been made substantial, and is largely of metal and aluminium, with an aluminium top. The grid is large enough to cover a 14×17 in. film, whilst the lead strips are only $2\frac{1}{100}$ ths of an inch thick and are claimed to secure an interception of some 85 to 90 per cent. of scattered peripheral rays. The grid allows of very considerable range of focal distance and of stereoscopic adjustment in both directions. In connection with the motor, there are timing and signal devices. For use on heavier parts of the body where long exposures are necessary, a compression device is also included. The cost, complete with all accessories, is £50.

'TABLOID' PHOTOGRAPHIC DESENSITISER.

PHOTOGRAPHERS, who are not able to have the convenience of a dark room, can develop their plates as easily as gaslight paper by using 'Tabloid' Desensitiser which has just been put on the market by Messrs. Burroughs, Wellcome & Co. For tourists and travellers it is most valuable, because development can be carried out in any room or cupboard from which light can be excluded for a minute. From ordinary dark rooms it removes the inconvenience of gloom and relieves the eyes of strain.

After one minute's treatment in the dark, development of the great majority of plates can be completed by candle light, or in the shadow of the body, in a room lighted by ordinary gaslight or incandescent electric light; ultra-sensitive and colour plates by bright yellow light, or, with care, even by candle light or dim gaslight.

The action of the Desensitiser is to remove a great proportion of the sensitiveness of the emulsion without destroying the latent image created by exposure.

One great advantage of 'Tabloid' Desensitiser is that it enables panchromatic plates to be developed in a comfortable light. It is issued in cartons of 25.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints of the literary pages of the "Gazette" gratis, if asked for at the time of submitting their manuscripts.

REPRINTS OF THE ARTICLE CONCERNED (ONLY), IN PLACE OF REPRINTS OF THE WHOLE OF THE LITERARY MATTER OF THE ISSUE, CAN BE SUPPLIED ON PAYMENT IF ASKED FOR AT THE TIME WHEN ARTICLE IS SENT IN. BUT AS THESE HAVE TO BE MADE UP SEPARATELY, THEY ARE NECESSARILY DELAYED.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

ABDOMINAL TUBERCULOSIS IN
INDIAN PRACTICE.*

By F. W. C. BRADFIELD, M.S., F.R.C.S.,
LIEUT.-COLONEL, I.M.S.,
General Hospital, Madras.

TUBERCULOSIS amongst cattle appears to be unknown in the Madras Presidency, and although no bacteriological investigations have been made, it is more than probable that this absence of bovine tuberculosis influences the incidence and character of the disease in South India. Tuberculous diseases of bones and joints, though not so commonly seen as in European hospitals, pursue a much more intractable course and are less amenable to non-operative forms of treatment. The economic problems of this country and the ignorance of people of the hospital class are contributory factors, but multiple lesions are more common and the surgical forms more frequently complicated by the presence of lesions in the lungs.

In 1924, 205 patients were admitted to the General Hospital, Madras, for surgical forms of tuberculosis or 2.1 per cent. of the total admissions. The sites of the disease were as follows:—

Abdomen	95
Lymphatic glands	39
Bones	35
Joints	28
Abscess (not classified)	3
Skin	2
Testis	1
Kidney	1
Larynx	1
Total	205

Abdominal tuberculosis (including enteritis 20) accounted for 95 of these patients or 0.97 per cent. of the total admissions to the hospital—a very much higher percentage than is found in European general hospitals, and a figure approximating to that of children's hospitals, where it generally averages from 0.05 to 2 per cent. of the total admissions.

The admissions to the medical and surgical wards were as follows:—

Tuberculous peritonitis	55
Tuberculous enteritis	20
Tuberculous cæcum	20

I have endeavoured to estimate the value of surgical treatment in what is undoubtedly a common form of tuberculosis in South India by a study of the First Surgeon's operation registers of the General Hospital for the past 6 years. These researches only show the type of disease found and the immediate results of operation. The difficulty of tracing Indian patients is very

* Being part of the Annual Surgical Report, Madras General Hospital, 1924.

great, but some idea of the ultimate results can be obtained from my personal notes. Most of our enquiries remained unanswered. One patient who replied some months after the notices had been sent, had been so alarmed at the receipt of a letter that he had only opened it when he considered a safe period had elapsed.

The results of operation have been as follows:—

	Total.	Mortality.	Ratio.
Tuberculous peritonitis	43	14*	32.5%
Tuberculous cæcum—			
Excision of cæcum	14	2	14.2%
Ileo-colostomy	6	0	0
Simple laparotomy	7	0	0
Cæcostomy	1	1	

* 3 died within three months of leaving hospital.

I. *Tuberculous Peritonitis*.—1. *Ascitic Variety*. Of 3 patients operated upon, one

PLATE I.

Tuberculous disease of cæcum showing extensive polypoid formation of the mucous membrane, also thickening with stenosis at the junction of ileum and cæcum.

with extensive involvement in the pelvis died after 2 months. This variety in its true form is comparatively rare, and not enough cases have been recorded to test the value of simple laparotomy, the treatment usually advocated. Operation, when fluid in the abdomen has been diagnosed, has generally revealed the presence of the numerous adhesions which characterise the next type

and in which the results of operative interference are very poor.

2. *Fibrous and Adhesive Variety.*—Of 40 patients submitted to operation, 11 died, a mortality of 27.5 per cent. Many of these patients were operated upon for acute complications. Perforation of tuberculous ulcers with resulting acute peritonitis accounts for 4 with 4 deaths, intestinal obstruction 5 with 3 deaths, infected tuberculous abscess 4 with 3 deaths. In 6 patients enlarged tuberculous glands were a prominent feature, and in two of these infection had taken place in chronic abscesses with fatal result.

PLATE II.

Tuberculous disease of caecum showing tuberculous fibroid infiltration of the wall with stenosis.

The average age of the majority of these patients (22 out of 39) was between 20 and 30 years. In typical cases diagnosis is not difficult. Abdominal pain, sometimes with definite relation to taking food, and fever are complained of, while a doughy, distended abdomen, often with evidence of free fluid in the peritoneal cavity, sometimes with a tumour mass or with peristalsis due to chronic obstruction are signs which cannot be mistaken. In the early stages a chronic dyspepsia, resistant to treatment and combined with tenderness in the right abdomen, may render diagnosis difficult, but the pain never has the relapsing character of that of a duodenal or gastric

ulcer. A tumour mass may call for an exploratory laparotomy, but the results, immediate and remote, with these patients are very poor.

II. *Tuberculous Diseases of the Cæcum.*—Ileo-cæcal tuberculosis as described by Hartman (to whom we owe the best description of this disease) is a form of tuberculosis very amenable to operative interference and more common than is generally recognised. A record of 20 cases in one year is evidence that the disease is very common in South India, though it is probable that many of these patients, who were not submitted to operation, were really extensive examples of fibrous peritonitis. The disease

PLATE III.

Tuberculous caecum showing stenosis and fibroid thickening.

occurs in two forms, in both of which a mass is found in the right iliac fossa. The *entero-peritoneal form* is an ulcerative caseous tuberculosis not confined to the caecum but attacking also the ileum and the appendix. The ileo-cæcal region becomes lost in a mass of adhesions, among which caseating cavities, often forming in the later stages pyo-stercoral fistulae, are found. This variety may simulate an appendicitis and the signs are those of an enteritis, never of obstruction. The lungs are frequently involved. Actinomycosis has never been seen in South India, but in other countries may produce similar symptoms. The *hyperplastic variety* simulates a

PLATE IV.

Ileocaecal tuberculosis. Hyperplastic variety.

neoplasm in the right iliac fossa and after a very vague, insidious onset, the symptoms are those of a chronic intestinal obstruction. Tuberculous foci are scanty, surrounded by a dense fibrous tissue mass and associated with other purely inflammatory lesions, as for example, dense sclero-adipose thickening and the production of numerous polypi and vegetations in the mucous membrane. The disease in this variety is confined until late to the cæcum, the walls of which are converted into a hard, rigid mass associated often with very extreme stenosis. Ulcers are sometimes found in the ileum and a similar hyperplastic condition

PLATE V.

Tuberculous cæcum with extensive thickening of the wall of the cæcum, and stenosis. Necrotic condition of mucous membrane.

may occur in other parts of the larger intestine. The lymphatic glands are often markedly infected.

The disease, as we have seen it at operation, has had the characters of the hyperplastic variety rather than of the ulcerating caseous entero-peritoneal form. There are a number of specimens of the disease preserved in the Medical College Museum, all of which show massive fibrous formation in the walls of the cæcum. Of 28 patients, whose operations were recorded, 6 were too ill or had too extensive mischief to allow of more than an exploratory laparotomy and cannot be classified. Five appeared to have been enteroperitoneal in character, 17 were

hyperplastic, one with involvement of the sigmoid flexure. An interesting point about all these patients is that the ages noted were from 25 to 35, except four aged 43, 45, 19 and 17. This agrees with Hartman's description that the disease presents its maximum frequency between the ages of 20 and 40.

My own records suggest that the hyperplastic variety is not so entirely confined to the cæcum as the original description would suggest, and this is borne out by the brief notes of the other surgeons. The reason, of course, may be that our patients are seen at a later stage than in a more educated European community. In 6 patients the disease was entirely confined to the cæcum, in two there were scattered ulcers on the lower part of the ileum, and in two, in addition to ulcers on the ileum, there were miliary tubercles distributed over the peritoneum of the small intestine. In the patient on whom a cæcostomy was done, the tuberculous mass was entirely confined to the splenic flexure, but on account of his poor general condition and the presence of a sub-acute obstruction no radical treatment could be attempted. In only 3 of these 11 patients was there obvious disease in the lungs. Colonel Niblock reported 1 patient in the entero-peritoneal variety, on whom a lateral anastomosis was completed with complete success. A further operation was performed on this patient some months after the original one, and the tuberculous mass was found to be entirely healed, no evidence of tubercle remained.

Of my 11 patients one died 5 days after cæcostomy, another patient, with extensive disease in the lungs, died on the 5th day after an ileo-colostomy. Of the remaining 9 patients (excision of cæcum) seven left hospital with apparently an excellent result. All the 9 patients were discharged from the hospital, and we have been able to trace the after-history of 5 of them up to 2 years.

Case 1.—Male, aged 36. Tuberculous cæcum, entero-peritoneal. There were several scattered ulcers on the ileum and miliary tuberculous nodules on the peritoneum. Tuberculous infection present in both lungs. The chief signs were pain in the abdomen, chronic diarrhoea, and a tumour in the right iliac fossa.

Operation.—Excision of cæcum with lateral anastomosis. The patient developed a faecal fistula at the site of operation and was discharged with this still not healed. He died 6 months after operation as a result of general tuberculosis.

Case 2.—Female, aged 38. Had been treated at a sanatorium for tuberculosis of the lung with improvement. History of a hard, fixed mass in the right iliac fossa for several years. Lately she has been subject to attacks of pain which commenced 1½ hours after food and were relieved by vomiting.

Operation.—Excision of cæcum with lateral anastomosis of ileum to transverse colon. Hyperplastic disease of the cæcum, but the coils of the

ileum in the pelvis were studded with tubercles and matted together. The pathologist's report says that the ileo-cæcal valve was stenosed to almost complete obstruction by hyperplastic tuberculosis. Following the operation she had a severe broncho-pneumonia, which caused considerable anxiety for some time but eventually cleared. A fæcal fistula developed at the wound, but this healed with careful dressing 2 months after the operation. This patient is still at the sanatorium, 18 months after the operation. Her general condition is slowly improving but she still gets fever after over-exertion.

3. Remaining cases; girl, aged 20, man, aged 45, and girl, aged 18, with typical hyperplastic tuberculosis 2½, 2 and 1 year after the operation. They all appear to be in excellent health and free from tuberculosis.

The treatment of these forms of ileo-cæcal tuberculosis should be surgical; if seen at a reasonably early period, the results will be very satisfactory, and the dangers of the patient developing further tuberculous lesions remote. Simple laparotomy is, of course, useless, and short circuiting or ileo-colostomy should be reserved for advanced degrees of the disease or for the entero-peritoneal variety which presents many difficulties, both on account of the adhesions in the abdomen, and the often extensive distribution of the tuberculous infection. Excision of the cæcum, including any involved area of ileum or ascending colon, is not a very difficult operation, and the divided ileum is joined either to the transverse colon or to the sigmoid loop. The average reported mortality from the operation varies from 12 to 25 per cent., and though we have had no mortality in our last 7 operations, 2 of these patients developed very alarming symptoms of severe toxæmia and were acutely ill for 48 hours. Handling of the tuberculous mass probably accounted for this condition, but recovery from the operation was otherwise very rapid and satisfactory. A two-stage operation does not appear to be necessary except for very feeble patients. Two of our patients developed fæcal fistulæ, an accident which I attribute to the drainage employed, and which I now endeavour, if possible, to avoid.

III. Two other unusual forms of abdominal tuberculosis in the period under review are worthy of note here. One patient with typical tuberculous ulcers in the upper part of the jejunum was operated upon under the mistaken diagnosis of duodenal ulcer. Another patient with symptoms mainly gastric was found to have a complete fibrous stricture at the ileo-cæcal valve. No evidence of tuberculosis could be found and the patient made a complete recovery after excision of the cæcum. We have not been able to trace the further history of this patient, but the condition as in 2 similar cases reported by Hartman, may have been tuberculous in origin.

I am indebted to Captain Bernard, Radiologist, Madras General Hospital, for photographs of

specimens which are preserved in the Medical College Museum.

SUB-PERIOSTEAL EXCISION OF JOINTS.

By H. HALLIWAY,

LIEUT.-COLONEL, I.M.S.

THE case, which is the text of this article, appears to be worthy of publication because it illustrates a principle and bears on a procedure on which surgical opinion is by no means un-animous.

Briefly the case history is as follows:—

The patient, a follower in the Mule Corps, was admitted to hospital as soon as he arrived in Bushire for an irreducible dislocation of the right elbow-joint, which he stated had occurred some six months before and three months previous to his enlistment. It was towards the end of the Great War, and in the dearth of men then prevailing, medical officers did not scrutinise the physical defects of recruits too closely. At any rate this man had been enlisted with an irreducible dislocation of the right elbow-joint, and his martial ardour having subsided by the time of his arrival in the Gulf, he recognised in his disability the finger of Providence, and sought an asylum in the nearest hospital.

Fig. 1.

The first skiagram shows a fracture-dislocation of the right elbow-joint, the articular surfaces being rotated forward.

Reduction being out of the question, it was considered that an excision would give him the best chance of a useful limb.

A sub-periosteal resection with a very sharp rugine was done on the 18th December, 1918. Kocher's incision was used. No soft parts were sacrificed, and the whole apparatus of the joint was left intact.

Indeed it was very difficult for visitors to whom this case was shown to believe that an excision had been done, so complete was the restoration of form and function.

The interest of the case, however, lies not so much in the result as in the principle which it illustrates, viz., that the regeneration of a joint is possible after an excision providing that the excision is done with a sharp rugine, so that the

Fig. 2.

Skiagram No. 2 shows the condition of the limb the day after the operation and the extent of bony removal. The limb was put up on a hinged splint which was discarded after a month.

Another skiagram, taken one month after the operation, showed an abundant growth of new bone, the new bone being laid down in such a manner as to replace the old bone which was removed in the excision.

Skiagram No. 3, taken six weeks after the operation, shows the restoration of the contours of the joint, the restoration of the ulnar process and of the internal and external condyles. As the callus was young, it did not throw a dense shadow, but the deposit of new bone was easily perceptible to touch, and the restoration of the olecranon process and of the condyles was complete.

All movements were completely restored and he obtained a very strong and stable joint.

Fig. 3.

cambium layer of the bone is raised with the periosteum.

The patient was a man of 27 years of age, so that the result appears to be in direct contradiction of Ollier's well known dictum that after sub-periosteal resection (of a joint) in an adult no new bone is formed.

Generations of medical students had been taught that it was to the periosteum that the regeneration of bone was to be attributed; and it was not until 1911 when McEwan's epoch-making communication came very much like a bolt from the blue that the comfortable and somewhat uncritical acquiescence of the profession in the older view was rudely shaken.

McEwan set out to prove that the periosteum takes no part in the regeneration of bone; far from it, its functions are entirely those of a limiting membrane.

He devised a number of ingenious experiments to show that the regeneration of bone is effected by bone alone. He even repeated Duhamel's ring experiment, with this modification that he first removed the periosteum, yet the ring became embedded in the shaft of the bone exactly as in Duhamel's experiment. Duhamel buried his ring *under* the periosteum, and when it became buried in bone he inferred that this growth of bone took place from the periosteum.

The undeniable clinical fact that in many cases when osteomyelitis occurs in the shaft of a long bone a sheath of new bone is laid down about the necrosed shaft, he explained by assuming that osteoblasts are carried out along the Haversian canals into the loose areolar tissue beneath the periosteum, and it is from these cells that the new bone is laid down.

When McEwan, nearly 45 years ago, built up the shaft of a boy's humerus by filling it in with wedge-shaped fragments obtained from osteotomies, he made a brilliant contribution to operative surgery and started surgeons on the road which has led to the achievements in bone grafting which are common-places to-day; but in his anxiety to impress the importance and true inner meaning of his discovery upon the surgical opinion of his time he was led, I think, into relegating the share taken by the periosteum in bone repair into an unfairly subordinate position.

It is not, I believe, generally known that some recent advances in the treatment of bone defects were anticipated by a Central Asian surgeon nearly 400 years ago. When the Emperor Baber was wounded in his retreat from Andejan by an arrow in the thigh, his uncle, the Khan, sent his own surgeon to examine the wound. I quote the Emperor's own words:—"To the wound in my thigh he applied the skin of some fruit which he had prepared and dried, and did not insert a seton. He told me that a man once had the bone of his leg broken in such a manner that a part of the bone, the size of a man's hand, was completely shattered to pieces. He cut open the integuments, extracted the whole of the shattered bone and inserted in its place a pulverised preparation; the preparation grew in the place of the bone, and became bone itself, and the leg was perfectly cured."

The Khan's surgeon does not say what the pulverised preparation was, but probably regeneration of the shaft took place from the periosteum or from the osteoblasts which were lifted with the "integuments."

Whether the new bone, which in certain circumstances is admittedly laid down by periosteum as in the case of the massive necrosis of a long bone, is derived from the periosteum or is developed from true bone cells fortuitously entangled in the deeper layers of the periosteum appears to be a matter of purely academic interest; a far more momentous issue is the capacity of the periosteum to regenerate the shaft of a long bone,

providing a special operative technique be adhered to.

How any one can doubt this who has read the works of Leriche and carefully studied his illustrations, it is difficult to understand, yet we are still treated to solemn warnings against the dangers of sub-periosteal removal of bone and the incapacity of the periosteum to regenerate fresh bone.

The worst of a negative injunction of this kind, presumably founded on a disastrous experience, is that if the experience is personal it must of necessity be a very limited one; it is difficult to believe that the surgeon persisted in a line of treatment which resulted in a succession of flail-joints and ununited fractures.

The burden of proof lies on the prosecution.

As Leriche himself says, "On this pitiful evidence it is decided that the sub-periosteal removal of fragments is useless. Need one point out the worthlessness of these careless conclusions? What is known of the conditions under which the operations were performed?"

On the other hand, the defenders of the theory can supply an abundance of clinical evidence that the periosteum properly elevated can re-constitute the shaft of a long bone.

What the disciples of the Lyons school claim is not unreasonable. They assert that if care be taken to raise with the periosteum sufficient cells of the cambium layer of the bone, these cells, placed in optimum conditions as regards site and nutrition, are capable of growth and survival.

To deny them this would be to condemn all bone grafting procedures as futile; if a cell will not survive under these very favourable conditions, it would be even less likely to do so when cut off from its normal blood supply.

If, in Sir Arbuthnot Lane's graphic and arresting phrase, the bony skeleton is nothing more than the crystallisation of lines of force, then the re-constitution of a bone in the manner described is not a matter for astonishment, for the same lines of force which determined the contours of the original bone will mould the growing cells into the same forms again.

Technique.—The best pattern of rugine for the purpose is Ollier's. Messrs. Down Bros. have made me a very excellent modification of Ollier's original pattern with a special long shaft and a finger rest and guard. The edge, of course, should be as sharp as a razor.

These rugines were copied from a modification of Ollier's original pattern devised by Major Pierpoint, I.M.S., at the Indian War Hospital, Ambala.

The whole secret of the technique lies in the use of a rugine with a razor-like edge, which must be applied very firmly to the bone, as it is essential that a sufficient supply of osteoblasts from the cambium layer of the bone be elevated with the periosteum.

An incision is made which will inflict the minimum of damage to the soft parts of the joint, and once this incision has been made the knife is laid down and the rugine is the sole instrument used.

The bones are denuded of periosteum up to the limit of what is to be removed, all ligaments, muscular attachments, etc., being elevated with the periosteum.

The articular ends of the bone are then sawn off and the resulting cavity packed with sterile gauze. The limb is then put up on a hinged splint and passive movements commenced on the third day.

As a rule, no sutures are used, the gauze is changed on the second day and discontinued after a week.

A NOTE ON THE DISINFESTATION OF HOUSES BY FUMIGATION WITH CRESOL.

By R. B. LAL, M.B., B.S., D.P.H., D.T.M. & H.,
and

C. D. TIWARI, M.D., B.S., D.P.H.

(From the Epidemiological Bureau, Punjab.)

THE method of disinfestation of houses for plague in vogue in the Punjab since 1915 is by vaporising commercial cresol on smouldering cow-dung cakes. Colonel Lane in a note on flea-destruction (1915) recommends two ounces of cresol for this purpose.

Under instructions from the Director of Public Health, Punjab, an enquiry on the efficacy of this procedure was undertaken in August last year.

The points studied by us were:—

(1) The effects of fumigation of varying amounts of cresol on rats and rat fleas in *pacca* (masonry) and *kachlia* (mud, etc.) houses; the fleas being:—

(a) in muslin bags

(I) directly exposed to the vapour; and

(II) more or less protected in various ways:

(b) on living rats,

(c) free in the room.

Experiments in Pacca Houses.—For this purpose two brick-built rooms of equal dimensions and of the same shape were selected in a residential house. The cubic capacity of each of these rooms was 1,488 cubic feet (124 square feet floor by 12 feet). They were well ventilated and well lighted. There was no dampness. The floor was made of brick-tiles without any cracks or holes and the walls were plastered and lime washed.

Fleas were caught quite uninjured in the following manner:—

A thick layer of freshly carded cotton-wool was spread on a small table. The fleas were collected in small test tubes directly from the fur,

while an assistant held the rat by the lower portion of its body and ears. Some fleas jumped on to the cotton-wool; these were picked up with forceps.

The general plan of these experiments was as follows:—

Free fleas, fleas in muslin bags (without folds), and rats with fleas on their bodies in Chitré pattern rat-traps were placed in various positions in the room according to the requirements of the experiments. Thus free fleas were placed—

(a) on the floor, directly exposed to the vapour;

(b) behind household furniture such as a log of wood, a *chakki*, a box, etc.; and

(c) in the folds of a *razai* (Indian cotton quilt).

Fleas in muslin bags were put—

(a) on the floor;

(b) in a rat run about 2 to 3 inches from the opening;

(c) in the folds of a *razai*; and

(d) behind the furniture.

The rat-traps were placed—

(a) on the floor;

(b) about 6 feet above the floor; and

(c) near the roof.

Messrs. Smith, Stanistreet and Co.'s brand of cresol was used throughout. On analysis it was found to be derived from fairly light oils and its phenol content was 44.5 per cent.

The rats employed were of the variety *Rattus rattus*.

All the openings were carefully closed. Wet and dry bulb thermometers were placed against a window-pane some time before the commencement of the experiment. The temperature having been noted, a variable amount of cresol was poured directly on to $1\frac{1}{2}$ seers of smouldering cow-dung cakes in an iron pan (*tasla*). The room was then sealed and kept closed for four hours in all cases. Looking through the window-pane the readings of the thermometers were recorded every half hour. On re-opening the room the condition of the fleas and rats was noted. Except in the case of the first four experiments, the fleas were kept overnight at room temperature and re-examined next morning to confirm the results of the previous day, for it was found that some of the apparently dead fleas were apt to revive.

In six experiments, Nos. 29, 30, 31, 32, 33 and 34 (using 4, 6, 8, 10 and 12 ounces of cresol) a sheet of cloth was stretched across the room at a height of $4\frac{1}{2}$ ft. in order to prevent the vapour from rising directly high up.

In nine experiments with 10 and 12 ounces of cresol the drug was distributed over two heaps of $1\frac{1}{2}$ seers of smouldering cow-dung cakes instead of one such heap.

Some preliminary experiments had shown that the fleas could live in muslin bags at room-temperature for at least 24 hours.

It was also ascertained that 4 ozs. of cresol took 40 minutes to vaporise completely when poured over $1\frac{1}{2}$ seers of smouldering cow-dung cakes. In view of this fact a uniform period of 4 hours was considered reasonable and convenient.

The summary of the experiments in *pacca* rooms is given in Table I.

Discussion of Results.—It will be seen that:—

(1) The rats remained unaffected, even with 12 ounces of cresol.

(2) Cresol vapour was definitely toxic to the fleas; 4 ounces were sufficient to effect the death of fleas in muslin bags placed 2 or 3 feet or more above the floor, but this quantity was

Explanation of signs used in the Table:—

Sign + indicates that the fleas all died.

Sign — indicates that the fleas were all living.

Sign ± indicates that some fleas were living and some dead.

Sign * indicates those experiments in which a sheet of cloth was stretched across the room 4½ ft. above the floor.

Sign @ indicates experiments in which in addition to cresol, sulphur ½ lb. and Sarson oil 2 ozs. were used.

Sign f indicates that the fleas did not leave the rat, and fl indicates that they left the rat.

Cresol was divided into two equal parts, in experiments in which in column 2 it is shown as such, as in experiments Nos. 10, 11 and 12, etc.

Sign .. indicates that that part of the experiment was not done.

Sign ? indicates that some fleas or all the fleas were not recovered.

insufficient to effect the death of fleas at floor level, and 6 ounces were required for this purpose.

(3) In traps placed on the floor, 8 ounces of cresol caused the fleas to leave the body of the rat completely, while only 4 ounces sufficed to make the fleas leave the rat when the traps were hung up 6 feet or more above floor level.

(4) While 6 ounces of cresol were sufficient to kill the fleas in muslin bags on the floor when directly exposed to the vapour, as much as 10 ounces were required to destroy them when the bags or free fleas were placed behind a box, a *chakki* or a log of wood, and even this quantity was not always successful when the bags were placed 2 or 3 inches inside a rat run. In the folds of a *rasai* free fleas or fleas in muslin bags were not killed, even when as much as 12 ounces of cresol was used.

(5) Mere smoke of cow-dung cakes without cresol does not affect the fleas or rats.

(6) The temperature during our enquiry ranged between 84°F. and 93°F. and the maximum variation of temperature during the course of any individual experiment was 9°F. Temperature within these limits does not seem to play any important part.

(7) Fleas in muslin bags placed in rat runs were more readily killed in experiments in which a sheet of cloth was stretched across the room than in other experiments with the same amount of cresol.

(8) Slightly better results were obtained by fumigation when any given quantity of cresol was vaporised in equal parts on two heaps of

cow-dung cakes than when the whole amount was vaporised on one heap.

(9) In two cases in which the doors were not perfectly closed, the efficacy of fumigation was distinctly reduced.

(10) Washing the floor with phenyl lotion killed the fleas on the floor.

Experiments in Kachha Houses.—For the first of these experiments two *kachha* rooms in a residential house were employed. The cubic capacity of each of these rooms was 1,300 cubic feet. The floor was unpaved but smooth and plastered with cow-dung and clay. They were full of typical household furniture and sundries like a *chakki*, a *charpai*, piles of earthenware pots, etc. There were some natural rat runs which were not closed. The walls presented an unbroken surface of plastered clay. The ceiling consisted of *sirkis* supported on rafters. Unfortunately, these rooms were not available for all the experiments and resource had to be made to somewhat less typical *kachha* rooms in a *zail-ghar*, when two rooms each of 10 feet by 10 feet by 10 feet were used. In this case the floor was unpaved, dusty, slightly broken in parts and not plastered with cow-dung. The walls were like the floor, with some peg holes. The ceiling consisted of bricks supported on wooden beams. They were fairly well lighted and ventilated.

The general plan of experiments was exactly the same as in the case of *pacca* rooms.

Here eleven experiments and one "control" experiment, using cow-dung cakes without cresol, were conducted. The summary of these experiments is given in Table II.

Explanation of signs used in the table :—As for experiments in *pacca* rooms, i.e., Table I.

Discussion of Results.—The results of the two series in *pacca* and *kachha* houses are not strictly comparable, but they are more or less similar.

(1) The rats remained unaffected even with the highest amount of cresol, viz., 11 ounces.

(2) To kill the fleas near the roof 4 ounces were sufficient, while 6 ounces were required to kill them on the floor. In one experiment there was evidence to show that some of the free fleas left on the floor escaped destruction even when 10 ounces of cresol were used.

(3) In traps placed on the floor, 10 ounces of cresol were required to make the rat free of fleas.

(4) Ten ounces of cresol killed the fleas in muslin bags placed two inches inside a rat run.

CONCLUSIONS.

1. Cresol fumigation as ordinarily carried out has no action on rats, but has a definite toxic action on rat fleas in muslin bags, free in the room, or on the bodies of the rats, but the quantity recommended by Colonel Lane, viz., 2 ounces, is quite insufficient for ordinary rooms of 1,000 to 1,500 cubic feet capacity.

2. Household furniture and rat runs afford effective protection to the fleas against the action of the vapour, even when the drug be used in large quantities.

3. Fumigation with cresol tends to cause fleas to leave their host.

4. The toxic action of cresol vapour is more manifest at higher levels as compared with the floor level.

5. Slightly better results are obtained by vapourising cresol on two heaps of smouldering cow-dung cakes instead of on one.

Recommendations.—To make the disinfection by cresol effective:—

1. Remove all the furniture and sundries before disinfection, and thoroughly expose them to the sun.

2. Use 10 ounces of cresol in an ordinary room of 1,000 cubic feet capacity.

3. Preferably distribute the drug over two iron pans containing smouldering cow-dung cakes placed in different parts of the room.

4. It is expedient to arrange some mechanical means for preventing the vapour from directly rising up.

5. It is necessary to seal the room carefully before fumigation, and to keep it closed for four hours afterwards.

6. It is expedient to wash the floor with phenyl lotion after the disinfection is over.

7. After disinfection is complete, rat runs should be fumigated with neem-cartridges and then closed.

It is recognised that without the help of the usual staff and under the rural conditions in the Punjab it would not be always possible to carry out these recommendations, and the value of this procedure is, therefore, limited.

YAWS (FRAMBOESIA) IN THE CHIN HILLS.

By P. BELL, I.M.D.,

Assistant Surgeon, Chin Hills, Falam.

LIKE many other diseases, yaws is a disease that occurs in certain districts. Its ætiology need not be repeated here, as books already exist where the subject may be studied, for instance, Spittels' "Framboesia Tropica." What I wish to point out here, is, when any suspicion of an unfamiliar disease is met with, it will probably be of benefit both to the medical profession and to the patients themselves, if this suspicion is examined, until results show one that the suspicion bears fruit or is groundless.

On arrival in the Chin Hills, I noticed that a certain class of cases occurring up to the latter part of 1923 (three months before my arrival), were being classified as "syphilis." Several were treated in the out-patient department, but as the custom of the Chins is to take medicine only when they visit headquarters on business, these out-patients are lost trace of, unless they return for treatment when visiting headquarters again. This may mean a long time, perhaps, a month or more. Taking this into consideration, I have not tried to include these cases. But, as with the in-patients, their symptoms and history in all cases have been similar.

It may be of advantage to give the usual symptoms of syphilis as met with in every-day practice and against them the symptoms met with in the cases here described. At a glance one sees the difference and concludes that a microscopical examination is unnecessary.

SYPHILIS.

CASES TREATED IN FALAM.

- (1) Primary infection in almost all cases genital, extra-genital cases are rare.
- (a) Angle of the mouth affecting the junction of mucous membrane, and skin not hard indurated or large, more like a chap or like a cracked lip.
- (b) Margin of anus, starting as a pimple and taking on a condylomatous appearance.
- (c) Some cases do get it near the genitals, some on the genitals. I have not seen one case of vaginal sore; they are always on the labia majora or sometimes mimora. In the male the groin is usually affected. In a few cases the patient has a sore on the foreskin or glans but these are like a soft sore.

In the great majority of cases though, the onset is ascribed to the anus, next the mouth then other parts. The Chin is simple-minded and even their woman folk readily show all affected parts without any pretence of being shy. Their re-

SYPHILIS.

CASES TREATED IN FALAM.

plies are usually straightforward when denying infection through immorality.

- (2) Secondary rash. (2) Not met with; though a child had a rash all over the abdomen. In some places it looked like a secondary rash. Taking the child's age into consideration, i.e., 2 years, it was not a case of congenital syphilis, as we know this shows within six months of birth, if the child is not born with symptoms of the disease. Was it acquired? The only means of infection, that I can suggest is through suckling. The mother's disease was more like yaws than syphilis.
- (3) Iritis. One is familiar with the blindness met with in Burma; many of these cases can be traced to syphilis. Why, is the Chin exempted? (3) Nil, not seen in a single case.
- (4) Teeth affection. (4) Not seen in a single case.
- (5) Itchiness .. (5) In some cases the patients did complain of itchiness but the Chin's habits are very dirty and they never wash. This may be the cause of itchiness in these few cases more than the disease.
- (6) Bone affections. (6) Not seen in any of the cases.
- (7) Gumma .. (7) Not met with.
- (8) Other rarer symptoms as paralysis, etc. (8) Not met with.
- (9) Infection not due to dirty habits and surroundings but to personal contact, i.e., coitus. (9) Cases Nos. 2, 8, 11, 12, 15, 16, 17 and 23 were not contacts. The Chins are unclean personally. Some I am told never wash their hands or faces. They eat anything, i.e., dogs, rats, etc. The meat is usually partially cooked. They eat raw flesh as well. It is interesting to note that intestinal worms are common among them.
- Their homes and surroundings are filthy: being spirit worshippers, advice and medicine is usually a failure with them. They are now responding to treatment after seeing the benefit that some of the cases have received after N.A.B. treatment.
- (10) Secondary symptoms very often ushered in with an attack of fever. (10) Only one patient gave a history of fever.

The spirochaetes, described in text-books, are really meant for the expert and I must confess that I have failed to demonstrate the spirochaete

of yaws in some of these cases from which I took scrapings, using Geimsa's stain. I will confine myself to the clinical diagnosis and leave it to the reader to agree with me or not. After perusal of these notes one wonders if the two cases described in the *Indian Medical Gazette* of December, 1923, by Captain Shah, I.M.S., as primary extra-genital chancre could have been yaws. I do not say his diagnosis was at fault, but on seeing so many extra-genital cases in the Chin Hills, it struck me as being peculiar, though the ulcer on the woman's mouth does not look exactly like those met with in the Chin Hills.

A Typical Case.—Onset usually a small pimple at the margin of the anus, which bursts, spreads and eventually involves the groin or private parts, some cases starting in the groin and on the labia majora. Some cases start with an ulcer as already described at the angle of the mouth. Two women stated that their breasts were affected first. No history of primary sore; sometimes whole families are affected. Males, females, and children appear to be affected equally, though females mostly apply for treatment. This, I think, is due to the Chin being exclusively a cultivator and a very poor one at that. Their produce is of the poorest of the poor, and hence they must work hard for a living; the males even when very ill have to carry on somehow for a living. The importance of this relating to treatment will be seen later. On glancing through the cases, here described, we notice the following:—

(1) The typical ulcer, as noted in text-books, "encrusted ulcer" is not always seen. They were seen in 4 cases only out of 23.

(2) The 2 cases of infection of the breast, stated to be the primary lesion, were mothers suckling children about 2 years of age. The lesion may have started as a bite from the child as the part affected was situated about where the child's teeth would be when suckling. The wound touched by the dirty hands of a crawling child may have supplied the infection. The Chin woman suckles her child till late. I have seen children of 2½ or 3 years of age being suckled.

(3) Ulcers at angle of mouth; these, like the affection of the anus, are almost constant. One angle of the mouth in affected, just a patch about ¼ in. to ⅓ in. in diameter, like a patch of stomatitis but not so white. These patches are very stubborn and are usually the last to yield to treatment.

(4) In 1 case part of the eruption looked like a syphilitic eruption, but the child was 2 years of age and as remarked above could only have acquired it through its mother.

(5) One case shewed ulcers of the groin. I saw similar cases to this in the out-patient department. It is curious to note that the men usually suffer at this place, whereas the women mostly on the labia majora or anus.

(6) The ulcers round the anus in all instances have the same history. In appearance they can-

not be distinguished from a condyloma, and affection on one side usually extends to the opposite side by contact. This is most constant in the cases that apply for treatment. Seen in 14 cases.

(7) In 2 cases the eyelids were affected for the most part, the upper lids shewing the appearance of an eczema, scaly, like psoriasis. Both cases did very well under treatment. Though the eyelids were badly infected, it is interesting to note that the eyes remained unaffected.

(8) In 1 case the typical horny-like yaws, as described in text-books was seen. Two cases had ulcers of the soles of the feet. They had passed the horny stage and had large sloughing ulcers on admission, which were still very painful but not as painful as before ulceration began. This is typical of yaws.

(9) Family history, etc. In all cases syphilis was denied. The patients are not shy to answer questions and willingly show the affected parts; as a rule, a younger sister or someone in the family is affected. Three cases were all unmarried and all virgins. One patient stated that her younger sister was affected and another had two brothers infected; their parents were free. Some of the villages round about Falam are supposed to be heavily infected, especially a village called Hairon.

(10) The disease appears to hang on for years. One case was of 2 years' duration. Still graver symptoms than those described are not met with.

(11) In all cases the patients were treated with novarsenobillon diluted with sterilized distilled water, direct into the vein with a 10 c.c. syringe, and without exception all improved almost immediately after treatment. Mercury was also used. But the beneficial change was always noted after the novarsenobillon treatment and they appear to appreciate the treatment. It is hoped that the news will spread sufficiently to afford help to these poor ignorant people.

(12) We are well aware of the fact that treatment of both diseases is the same. From a moral point of view the 2 diseases should be differentiated, where possible, and handled with intelligence. In conclusion, I wish to refer to 2 cases of male patients admitted to hospital for treatment.

Case No. 1.—Chin male, aged 35, was admitted for treatment of the following:—

(a) Of primary importance to the patient was a large sloughing irregular ulcer with raised margins, parts of which had a warty appearance, parts undermined with pus covered with small scabs, the centre had several raised warty looking growths on it with others surrounding the ulcer, situated on the inner side of the right ankle, extending back to the heel and tendo Achillis, and forward just beyond the middle line, upwards about 3 finger-breadths above the malleolus, and downwards to the junction of the sole of the foot. The patient was unable to walk from severe pain, and had in addition a constant weeping condition of the part.

(b) Warty growths on the forehead, around the nostrils, and mouth and at the outer angle of the right eye. Ulcers in nostrils.

(c) Elevated ulcers with pus and scabs on the wrists, forearms and face.

(d) Ulceration of fauces, especially on the left side.

(e) Ulcer at tip of tongue, under surface.

(f) Warty patches in the right axilla.

(g) Ulcers on the foreskin with a whitish discharge. He was unable to pull back his foreskin. The discharge did not contain gonococci. His features were slightly bloated and his conjunctivæ were injected. He was in great pain at the time of admission. Positively denied having contracted syphilis and stated that his wife was not infected. The leg was dressed and I gave him tincture iodine m. vi. intravenously, repeated the next day with m. vi. for experimental purposes. As there was no immediate result and being quite positive that the case was one of syphilis, I next gave him an intravenous injection of novarsenobillon. The pain in his leg subsided altogether and the part dried up. He was doing well. The condition of the tongue, angle of eye, nostrils and mouth were rapidly cleaning up. Unfortunately for him, his father came to hospital and took him home, because his wife was about to be confined and he had to perform some religious ceremonies, and could not be left in hospital until completely cured. This case I believe was one of syphilis and not of yaws.

Case No. 2.—Chin male, 56 years of age, a sturdy old man and in good health except for an enlarged right knee for which he sought treatment. Duration 6 months. Had marks of blistering, etc. Very good movement in the joint. No riding of the patella. Inflammation of inner part and below patella mostly. Knee much larger than the left one. Shiny appearance, most painful on the inner side. I ran a 10 c.c. needle into the most painful part but nothing came away, not even fluid. I then aspirated below the patella with no result. He gave a history of syphilis many years before. On examining his penis for marks of sore, I noticed that the whole of the tip of the foreskin had the appearance of a fairly recent infection. Like all other Chins, he left hospital before being completely cured.

Since writing this article, there have been several admissions to hospital for similar cases and several relapses.

REPORT ON A VISIT TO THE LEPER ISLAND OF CULION AND ON THE ANTI-LEPROSY WORK IN THE PHILIPPINE ISLANDS.

By Dr. E. MUIR, M.B., Ch.B., M.D., F.R.C.S.,

Leprosy Research Worker, Calcutta School of Tropical Medicine.

THE anti-leprosy work which has been carried out in the Philippine Islands during the last 19 years is valuable not only for what it has done to stamp the disease out of these islands, but also for the stimulus which it has given to similar work in India and in other parts of the world. It was, therefore, with keen expectation that I looked forward to my visit to the leper island of Culion.

The Americans, on their occupation of the Philippine Islands, noticed the large numbers of lepers frequenting public places and engaged in occupations which rendered them a danger to the general community, and it was determined in

1906 to remove this menace by the deportation of all bacteriologically positive lepers to Culion, an island some 200 miles to the S. W. of Manila.

This policy has been carried out for the last 19 years, and those engaged in anti-leprosy work in the Philippines are of the opinion that, while the ardent expectations of some of those who initiated the work have not been fulfilled in reducing leprosy to negligible proportions, the results have justified the steps taken in the very considerable reduction of its prevalence.

As my experience in anti-leprosy work has been almost entirely confined to India, this report will take the form of a comparison of conditions connected with leprosy in India with the corresponding conditions in the Philippines, as far as I was able to become acquainted with them during my very short visit.

There are 11 million inhabitants of the Philippine Islands, and it was estimated in 1906 that there were some 10,000 lepers in the islands or, roughly, 1 in every 1,000 was a leper.

The Indian census of 1921 gives an estimate of an average leper population of about 1 in 3,000, but those who have had the most opportunity of judging are of the opinion that 1 in 600 or even 1 in 300 would be a more correct figure.

With a population about 30 times as great and with a proportional endemicity perhaps 3 times as great, the problem in India is a very different one from that in the Philippines. Any attempt to follow the example of the smaller country in carrying out general segregation would obviously be impossible, and it may, therefore, be useful to mention briefly what methods it is proposed to adopt in India.

We have no reason to believe that leprosy is either rapidly increasing or diminishing in India, and if we assume what is probably the case, that it is at a standstill, it would mean that one leper in one generation infects, on an average, one healthy person in the next generation, and thus a balance is kept up. I believe that, if the programme that we propose is carried out efficiently, this balance will be upset and the disease will entirely disappear within a few generations.

Two most potent factors which make for the continuance of leprosy are the ignorance of medical practitioners and still more of the general public of the early signs of the disease, and the general prejudice which there is against leprosy as compared with other more transmissible and more fatal diseases. Medical students are given no practical training or clinical demonstrations which would enable them to make an early diagnosis, and many doctors have such a horror of the disease that they would not willingly undertake its treatment. Although leprosy is a far less communicable disease than tuberculosis, the superstitious dread of the former is so great that those known to be suffering from it are ostracised and, even before the disease has reached a stage

at which it is possible to find the bacilli on bacteriological examination, they are removed from their employment and thus placed in the very circumstances which are most favourable for the rapid increase of the disease. For we find in India that, in the great majority of cases, the disease may be diagnosed clinically from signs of nerve origin at a stage when carefully made bacteriological examinations are negative, and the patient has, presumably, not yet become a possible source of danger. It is found, moreover, that the great majority of such early cases, when they are efficiently treated at out-patient clinics for a sufficient time, lose all active signs of the disease, and, provided they are able to remain free from other diseases and otherwise maintain a normal amount of general resistance, remain free from such signs for an indefinite period. Though it would be unwise to speak of such patients as "cured," yet there is good reason to believe that the longer the time they remain sign-free, the less is the likelihood of recurrence.

It will thus be seen that, if a negative bacteriological result carried out by a medical man with sufficient experience relieves the early cases from the necessity of being isolated, and if the early signs of leprosy are widely known and recognised by medical men and by the public, and if doctors who are able to treat the disease efficiently are available for all, we should have the means of cutting off the transmission at its source, which is always the ideal method of dealing with a disease.

We are, therefore, putting the chief emphasis in our campaign in India in this direction, and our programme may be classified under 6 heads:—

(1) The appointment in each of the 9 provinces of an expert, who shall be a man of energy and personality, and who shall be responsible for the initiation and organisation of leprosy work in the province.

(2) The training of doctors and students by the experts.

(3) The establishment of out-patient skin clinics where suitable cases may be treated.

(4) The establishment of one or more leper colonies in each province.

(5) Propaganda work by preparation and distribution of suitable literature, through the co-operation of the educational authorities and teaching in schools, through various health authorities, and above all through the trained doctors, the out-patient clinics and the leper colonies.

(6) Research work, which, though it is placed last in the list, is to be considered the most important of all.

As regards treatment—leper patients may be divided into 4 groups:—

(1) Those who are bacteriologically negative and who can obtain expert medical assistance either from private practitioners or at out-patient clinics, within reach of their homes.

(2) Those who are bacteriologically positive,

but are able to isolate themselves in their homes and obtain local expert medical assistance.

(3) Those, bacteriologically positive or negative, who cannot get efficient treatment locally and those, bacteriologically positive, who cannot effectively isolate themselves in their own homes.

(4) Those who are unable to support themselves or whose relatives have refused to support them because of deformities, dread of the disease or other reasons.

Classes 1 and 2 should preferably be treated in out-patient clinics, and classes 3 and 4 in colonies or other segregation institutions.

Colonies will be situated within the province which they supply; each colony will be limited to 1,000 inmates and have a superintendent and a well trained, high grade medical man with at least 2 qualified medical assistants. Colonies will be on sites of at least 100 acres with good land for agriculture and the raising of cattle, etc., and a sufficient water supply. Inmates will be encouraged to take part in agricultural, horticultural or industrial pursuits, and provision will be made for education and practical training. Abundant, suitable work and exercise will be provided, and fresh vegetables and dairy produce,—very necessary articles in the diet of those suffering from leprosy,—will be secured by the labours of the patients themselves.

Compulsion will not be used in sending patients to these institutions, except in the case of pauper lepers and of those who persist in endangering the public by carrying on certain trades; but, when necessary, compulsion will be used in carrying out discipline within the colonies and in the early removal of new-born and symptom-free children from bacteriologically positive parents.

Cases which are bacteriologically negative or nearly so, will, as far as possible, be separated from those with the grosser skin types of the disease.

Having thus outlined our proposed programme for India, which has only as yet begun to materialise in some of the provinces, I shall place alongside of it the methods which are at present in use in the Philippines, along with other schemes which I have been informed are contemplated there, and compare, as far as I am able, the differing conditions in the two countries.

As far as I have been able to ascertain during my brief visit, the following are the main differences between the leprosy problem in the Philippines and that in India:—

1. The number of lepers to be dealt with both absolutely and relatively to the whole population.

2. The limitation of the disease in the Philippines almost entirely to poverty-stricken classes of the people and its comparative rarity among the socially higher classes; whereas in India all classes are affected, the very highest not being excluded.

3. The more rapid onset of the disease in the Philippines and the consequent impossibility of

diagnosing it by clinical signs before it is possible to make a positive bacteriological examination. I was told that this is the case by those in charge of the work in Culion Island. It would imply an almost entire absence of patients of class 1. Now this last difference is one which I find myself unable to accept without further investigation. It is true that such cases are not commonly seen in Culion; but, when I visited the San Lazaro Hospital for lepers in Manila, I saw a possible explanation.

In this hospital there are more than 400 leper inmates, the great majority of whom have presented themselves voluntarily for treatment on the understanding that, if they become negative within a certain period, they will not be deported to Culion.

Now, according to the present law in the Philippines, a leper is only a leper when lepra bacilli can be found on bacteriological examination. Cases of leprosy, which in India we should diagnose on clinical grounds because of anæsthesia, nerve-thickening and other signs of nerve involvement, are not recognised as cases of leprosy in Manila; they are not admitted to San Lazaro Hospital or other leper institutions or treated by Government doctors until they are found to be bacteriologically positive.

I was told by one of the doctors in charge at San Lazaro that there are large numbers of such clinically positive but bacteriologically negative cases in Manila, and that in cases admitted to San Lazaro there was a history of clinical signs of the disease for an average period of about one year previous to their becoming bacteriologically positive. Now this would correspond more or less closely to what we have found in different parts of India—in Calcutta, in the Deccan and in South India among various races and in different climates—wherever leprosy patients have been attracted for treatment by efficiently run, voluntary out-patient clinics.

Before we started a clinic in Calcutta we had no idea that such cases existed in such numbers; and I am inclined to think that there might possibly be a similar finding in Manila and other places in the Philippines, if voluntary out-patient clinics were opened at various centres and run by first-rate doctors who had had extensive experience in the clinical diagnosis of leprosy from early clinical signs, as well as in the best methods of treatment. However, I think that no dogmatic statement should be made one way or the other before such an experiment has been made.

If such cases exist, it would only be natural that many of them should hide their malady out of fear of forcible detention, or should fail to recognise the significance of early signs, especially as they are not officially recognised in making the diagnosis.

It is obvious that the point is one that it is important to clear up as such cases do not need

to be segregated and are by far the most amenable to treatment; while by treating them the disease may be cut off at its source.

I think that a step in the right direction has been taken by establishing institutions like San Lazaro which are not so far removed from the homes of the people, but our experience in India, so far as it goes, lays great stress on the importance of abundant vigorous exercise in the treatment of leprosy and of mental and physical occupation, and I am not sure to what extent this can be carried out in institutions which are founded on the principle of the hospital ward, as at San Lazaro.

I believe that the principle of supplying exercise and occupation is being developed in connection with the Culion Colony, where many of the lepers are living on small farms and are engaged in fishing, market-gardening and other active employments. I am also glad to hear that there is a prospect of a road being opened up from the colony to another part of the island, which will further facilitate settlement on the land.

Another proposed development, which I consider of great importance, is the formation of facilities for the early removal of the children from their leprous parents to Manila, as many such children have in the past fallen a prey to the disease through contact with their leper parents or other lepers. Our experience in India points to the great importance of such measures in preventing the disease, and of making arrangements for the proper care of such children from earliest infancy.

I was greatly impressed with the efficient way in which pathological research is being carried out by Dr. Wade and his staff. I am deeply indebted to him for all that he taught me in this direction, I feel strongly that anything which is done to help and develop the work that he is doing will be of the greatest importance not only in the Philippines but wherever leprosy exists, and his work has its importance not only in connection with leprosy but in its bearing upon other diseases which are associated with leprosy.

It may not be out of place to mention here a scheme which Dr. Wade is initiating, a proposal for the early circulation of papers written by those engaged in leprosy investigation, so that such workers throughout the world may be informed of each other's results without the delay of waiting for publication in medical journals. It is hoped that in this way much waste of time and money will be avoided by preventing the unnecessary reduplication of work.

My visit has impressed upon me the importance of such personal conferences of research workers and the great possibilities of their results. I hope that it will be possible for us to welcome in Calcutta some of the workers from the Philippines.

My thanks are due to Dr. Avellana, the head of the Colony, and to Dr. Rodrigues, the chief physician; also to Dr. Perkins for all that he

showed me of the very important work that he is doing from the chemical side; also to the other members of the medical and pathological staff.

Above all, I wish to thank General Wood, Governor of the Philippine Islands, for his kind welcome and for all the facilities that he made for my visit to the Island of Culin.

CARREL'S TREATMENT AND ELECTROLYTIC CHLORINE AS AN ANTISEPTIC.

By Dr. ERNEST F. NEVE, M.D., F.R.C.S. (Ed.),
Senior Surgeon, Kashmir Mission Hospital.

THE introduction of "Electrolytic Chlorine," "E.C.," should give a great impulse to the treatment of septic wounds. There has been no greater advance in surgery as the result of war-time experience than what is known as "Carrel's method of irrigation of septic wounds with hypochlorite solution."

This treatment is absolutely based upon the principles enunciated by Lister. Dakin and Daufresne(1) proved by a very careful series of experiments that hypochlorite of soda in the presence of blood serum has approximately thirty times the sterilizing power of carbolic acid with reference to staphylococci, streptococci, the *Bacillus pyocyaneus*, and Welch's bacillus. It is true that perchloride of mercury is still more powerful, but this drug loses its strength so rapidly in contact with proteins and is so irritating that hypochlorite holds the field.

As the result of these researches, but also after careful observation of the direct action of various antiseptics on wounds, Dakin's solution finally emerged as in many respects the most satisfactory antiseptic. The special value of this fluid was that the alkaline, caustic element, present in ordinary hypochlorite solutions, had been eliminated, and in this way its irritant properties had been reduced to the minimum. This was most important, because the constant contact of a half per cent. hypochlorite solution with a wound surface is essential, if sterilization is to be effected. The hypochlorite combines, of course, with the proteins of wound tissues and secretions, and it is this which necessitates the continuous irrigation which is the characteristic of Carrel's method. Not only does such irrigation progressively destroy microbes, but also, as shewn by Lumiere,(2) it renders their toxins inert. In one striking experiment he inoculated pus from a case of severe tetanus into guinea-pigs. The pus was mixed with equal parts of 0.8 per cent. solution of common salt, and when injected into guinea-pigs caused death in 8 to 10 days. That, however, which was mixed in equal proportions with 1 per cent. hypochlorite solution and after an interval of one hour injected into other guinea-pigs proved quite harmless. In both experiments 1 c.c. of pus was used. This is only the illustration of many similar experiments dealing with a variety of microbes.

Staphylococci in aqueous suspension are killed by a hypochlorite solution of one in half a million.

It will be remembered that Carrel controlled his clinical use of this fluid with the microscope. He proved that in septic wounds, continuously and effectively irrigated with 0.5 per cent. Dakin's fluid, the number of microbes per field progressively diminished until, when there were only half a dozen per field or less, such wounds were practically sterile, and in many cases suitable for suture, which was followed by union by second intention.

Dakin's hypochlorite solution, although harmless subcutaneously, is most dangerous if injected into the general circulation, as it is hæmolytic.

The method of application to wounds is now familiar to many surgeons. The essential is that it must be distributed to the whole surface and the distribution maintained. This is, of course, very difficult where the wound area is irregular and contains diverticula, sinuses or lines of extension along planes of fascia. This is the crucial difficulty of Carrel's method of treatment. The branched glass distributing tubes and perforated rubber instillation tubes through which the solution is run over the whole of the wound, are now well known. If the technique is carefully carried out (and this is a very large "if"), splendid results can be obtained, and not only lives saved, which would have succumbed to septic toxæmia, but wounds which were profoundly septic can be rendered practically aseptic.

Before the introduction of "E.C.," Dakin's solution had to be prepared from bleaching powder of uncertain and varying chlorine content. Constant tests were required to ascertain the percentage of hypochlorite in order to maintain the 0.5 per cent. strength of the solutions used.

The introduction of "E.C." has changed all this. Pure "E.C." is, however, irritating in its action. It provokes serous discharge and discolours tissues, but without causing serious loss of vitality. A 20 per cent. solution should be used for irrigation of septic wounds by Carrel's method. A 10 per cent. solution of "E.C." is suitable for cleansing hands and preparing operation area: 5 per cent. is good for ward lotions and surgical dressings, but 1 per cent. is really adequate. For irrigation of the bladder or confinement cases 1 in 1,000 to 1 in 5,000 may be used.

For latrines 1 in 5,000 is most useful. The germicidal strength for *B. coli communis* is 1 in 75,000. For sterilization of water 3.06 m. per gallon or 19.2 m. per cubic foot may be used.

These and similar uses of E.C. are discussed in an important article by Col. Mackworth in the *Indian Medical Gazette* for October, 1922, and in the same journal in December, 1924, Major Napier gave an interesting series of cases illustrating the value of "E.C." in hospital work.

An important article by Hodgkinson and Hutchinson describes in full detail how unlimited

supplies of hypochlorite solution of 2.5 per cent. of available chlorine strength can be prepared from 25 per cent. bribe, 1 per cent. lime hydrate and 0.1 per cent. saturated solution of sodium rosinate by electrolysis, using a high current density of at least 1 ampere to the sq. cm. of the graphite electrodes and keeping the solution cool so as to avoid decomposition of hypochlorite. In this way the authors showed that a stable solution of much greater available chlorine content could be obtained than that obtainable under the conditions usually found in ordinary electrolytic cells, which have been designed to turn out large amounts of low strength solutions, mostly for commercial use.

The new "E.C." standardized at 2.5 per cent. available chlorine has this great value, that it can be used in surgical and other work with confidence. In order to obtain preparations of similar reliability, the principles laid down by Hodgkinson and Hutchinson(3) must be observed. Any failure to do so, may involve not only loss of chlorine percentage but also of hypochlorite. With due attention to current density and adequate cooling arrangements, improvised apparatus may be possible. Stevens, (4) for instance, of Miraj, describes such an arrangement by which 2 per cent. "Electrolytic Chlorine" may be obtained. There is risk in ordering installations other than those designed by Hutchinson, of finding that the output of "E.C." is not only below the specification, but that it is even considerably less than 1 per cent.

A cell with ten chambers and graphite electrodes which I imported from a well known firm in London, although stated to produce 2.5 per cent. "E.C.," only gave 1 per cent. after careful adjustment. Any solution above 0.5 per cent., if of constant strength, is useful, and the degree of dilution can be adjusted. It is, however, of first importance always to know what the amount of concentration really is.

As electrolytic cells are liable to vagaries, and the output may vary from time to time in its strength, it is necessary to test the "E.C." systematically to ensure its being up to standard. The same applies to the supplies of "E.C." which are now on the market. This is also of special importance in view of the deterioration which results from exposure to heat. At a temperature of 30°C, however, it keeps its strength for 6 weeks, and below 22°C for a year.

The following tests may be employed:—

Titration to Estimate Available Chlorine and Hypochlorite per cent.—Measure 10 c.c. of the solution, add 20 c.c. of 10 per cent. solution of iodide of potassium, 2 c.c. of acetic acid, then drop by drop a decinormal solution (2.48 per cent.) of hyposulphite of soda up to decoloration. The number (N) of c.c. used, multiplied by 0.03725 gives the percentage of hypochlorite, and N multiplied by 0.0355 = active chlorine per cent. Another test given by Hutchinson is the following:—

Standard Sodium Thiosulphate Solution.—Dissolve 14.1 grams of pure sodium thiosulphate in re-distilled water and make up to one litre. Standardise by titrating against pure iodine (say, about 0.2 grams dissolved in potassium iodide solution).

The number of grams of iodine multiplied by 140 should equal the number of c.c. of $\text{Na}_2\text{S}_2\text{O}_3$ required to render the solution colourless.

Procedure.—Pipette 2 c.c. of E.C. into an Erlenmeyer flask; add 5 c.c. of a 10 per cent. solution of potassium iodide and add 5 to 8 drops of glacial acetic acid. Now add $\text{Na}_2\text{S}_2\text{O}_3$ solution until the liquid is quite colourless. The number of c.c. of $\text{Na}_2\text{S}_2\text{O}_3$ used up, divided by 10 gives the percentage of available chlorine in the sample.

The former method is simpler, the latter is useful as a control.

TREATMENT OF VARICOSE VEINS OF THE LEG BY AN OCCLUSION METHOD.

By D. R. KEHAR,

CAPTAIN, I.M.S. (T.C.),

As a surgical specialist in Waziristan and Palestine, I had the opportunity of performing the radical operation for the treatment of varicose veins of the legs on about fifty cases, both British and Indian soldiers, but almost always found that convalescence was very prolonged.

This result, in my opinion, was mostly due to the defective blood supply of the skin immediately over and near the varicose vein and, therefore, diminished resistance to any pyogenic organisms which may be left at the time of operation. Moreover, in some cases the scars formed after the radical operation broke down and led to troublesome ulceration.

Last year, I tried the occlusion method on ten cases and found that the results were very encouraging and the patients were very comfortable during the period of treatment.

Technique.—The leg to be operated upon is shaved the night before operation and painted with tincture of iodine. Next morning when the patient is brought to the table, the leg is cleaned with spirit and painted with tincture of iodine again. A tourniquet is applied above the knee loosely to make the veins prominent.

Anæsthesia may be local or general.

The only instruments required are:—Wakley's fenestrated artery forceps, one pair; and some stout half curved needles threaded with strong No. 5 silk thread ligatures.

As soon as the patient is under the effect of the anæsthetic, Wakley's artery forceps are applied round the vein along with the skin and clipped. The vein, along with the skin, is then lifted up from the underlying structures by a pull on the forceps. Then a needle threaded with strong No. 5 silk thread ligature is passed underneath the vein and the ends of the thread are tied over it. In this way sutures are applied to the vein from above downwards, the sutures being half an inch to three quarters of an inch apart. The patient is then returned to bed.

Result.—The veins begin to shrivel up in about seven to ten days and get completely shrivelled up in about three weeks. The patient need not be confined to bed all this time. I usually keep him in bed for about forty-eight hours.

About ten days after the operation alternate sutures, beginning at the second suture from the top, are removed and the rest in about three weeks.

This method is very useful in the treatment of varicose ulcers as the shrivelling up of the veins relieves the skin over them of their constant pressure and allows the establishment of free circulation of blood. The ulcers under these circumstances quickly heal up under ordinary aseptic and antiseptic treatment.

DIABETES AND INSULIN TREATMENT IN BENGAL.

By Dr. LAL MOHAN GHOSAL, I.M.S.,

Demonstrator of Physiology, Medical College, Calcutta.

INSULIN treatment in diabetes has now become common practice, but in Bengal, so far as my experience goes from both hospital and private cases, not much benefit has accrued from it. This is not only my experience, but it is the experience of many other general practitioners in Calcutta. In Europe, on the other hand, insulin is being extolled to the highest degree as a treatment for diabetes. In America, too, where the drug was discovered, it is recognised as a remedy for diabetes, if properly used, although savants such as Maclean and others, while recognising that it is not a cure for diabetes, yet accept it as a beneficial agent in the treatment of diabetes. The question naturally arises why it is that in Bengal where diabetes is so prevalent such beneficial results are not obtained; in many instances no benefit at all has been derived either in reducing blood sugar or urinary sugar even with strict dietetic and other regulations.

The idea of insulin treatment was first suggested in Minkowski's experiment which showed that deficiency in the internal secretion of the pancreas was responsible for diabetes from the degeneration of the islands of Langerhans. Following out this theory, insulin was discovered in extracts of the islands of Langerhans. This extract was found to be glycolytic and the discoverers claimed admirable cures of diabetes.

But alas, in India the results are far from what was expected. Very few cases are known to have derived benefit from it—far from being cured.

Is it that the diabetes that is generally found in India and particularly in Bengal is not due to any pancreatic defect? It occurred to me to investigate if it is possible to find any means by which the pancreatic defect could be detected. There is, so far as is known, no direct means to determine it, but the Cammidge reaction in the stools suggested itself to ascertain whether pancreatic defect was present in Bengali diabetics.

The following is the result of this investigation.

I divided the cases into the three following categories:—

Group I. Very marked pancreatic defect without diabetes.

Group II. Diabetes without any pancreatic defect.

Group III. Diabetes with pancreatic deficiency.

Group I. Marked pancreatic defect without diabetes.

Case No. 1.—A patient with pain in the right hypochondriac region and a tumour-like mass. I examined the stool and urine for the Cammidge reaction and found the following results:—

Pancreatic deficiency	.. 76 per cent.
Intestinal deficiency	.. 66 per cent.

The urine was positive to the Cammidge test, but no glucose was found. I hazarded the opinion that the case was one of tumour at the head of the pancreas; of course I had not seen the case and did not know the previous history at first; the case was admitted into hospital; was operated upon and a big cyst was discovered at the head of the pancreas; the cyst was removed and the case was completely cured. I learnt this subsequently when he came with the stool for examination and gave a detailed story of his case. His stool showed this time the following result:—

Pancreatic sufficiency	.. 80 per cent.
Intestinal sufficiency	.. 72 per cent.

In this case it may be noted that with such pancreatic insufficiency and with a tumour in the pancreas he never showed glucose in urine.

Case No. 2.—An Anglo-Indian in Government employment, had suffered from diarrhoea for a year with very loose stools with occasional mucus. He was very thin and emaciated; and had had injections of emetine and a course of streptococcal vaccine; he had been diagnosed as a case of sprue; but no benefit resulted from any of the treatments. He came to me and I examined his stool and found the following result:—

Pancreatic deficiency	.. 78 per cent.
Intestinal deficiency	.. 70 per cent.

His urine never showed sugar in spite of such marked pancreatic deficiency. He was put on to a regulated milk diet for three months and was completely cured.

Case No. 3.—A European, manager of a big bank, had alternate attacks of diarrhoea and constipation which made him very thin; there was complete anorexia; whatever he took as food he vomited two hours later; of course he was living on European diet. His stool

and gastric contents were examined. His gastric contents showed deficiency in acidity and ferment activity, whilst the stool showed the following results:—

Pancreatic deficiency	.. 67 per cent.
Intestinal deficiency	.. 60 per cent.

There was no sugar in his urine. He was put on to a simple milk and fruit diet and recovered in the course of three months; then he went away to England. He is still alive, as his name is mentioned in a big bank case.

Case No. 4.—A. C. C., a clerk, had alternate attacks of diarrhoea and constipation for one year, then constant diarrhoea with frequent stools and griping for three months; sometimes he passed bloody and mucoid stools. Injections of emetine were given; a course of treatment with streptococcus vaccine from a strain isolated from the stools was given; but with no effect. Tuberculosis was then suspected and a course of tuberculin was also given but without benefit. His stools showed the following results:—

Pancreatic deficiency	.. 90 per cent.
Intestinal deficiency	.. 80 per cent.

With such virulent pancreatic deficiency he never showed sugar in the urine; the Cammidge reaction in the urine was also negative. He finally died.

Case No. 5.—A. C. M., manager of a big estate—suddenly developed diarrhoea with dyspepsia; he was treated with various remedies but without improvement. His stools showed the following results:—

Pancreatic deficiency	.. 70 per cent.
Intestinal deficiency	.. 70 per cent.

He changed his treatment and was finally relieved by Kabiraji treatment and a change.

I might cite numerous other such cases, but as the list becomes a heavy one I select these typical cases. In such cases we find that although there is severe pancreatic deficiency, due either to organic defect of the pancreas or to functional defect of the organ, there is no diabetes or glycosuria in any of these cases at any period.

Group II. Diabetes without any pancreatic defect.

I will next cite patients who had had diabetes for years and years together without any pancreatic deficiency, and they were long lived and held important positions in life.

Case No. 1.—P. B., head clerk in a very important office, contracted diabetes at the age of 45 and died at the age of 82; all the while he was working in his capacity as head clerk, except for the last two or three years of his life when he was forced to take rest by his sons who have all attained to great eminence. I examined his stools thrice at different intervals and at no time was there any pancreatic deficiency found; the following was the result of examination of his stool:—

Pancreatic deficiency	.. 26 per cent.
Intestinal deficiency	.. 32 per cent.

Case No. 2.—Rai Sahib C., a big zemindar, living a luxurious but careful life; in his younger days he had been manager of a big colliery estate which was much encumbered; by his administration the estate became a solvent one and the income rose from Rs. 12,000 to Rs. 60,000 a month. He contracted diabetes at the age of 42 and is still living, his age being now 65. He left the service of the estate at 44 and is now managing his own estate which is worth not less than 50 lakhs. His urine and stools I examined frequently and there was never any pancreatic deficiency detected. This is a very good case suggesting that mental strain plays an

important part in the etiology of diabetes. Examination of his stools gave the following result:—

Pancreatic deficiency	.. 20 per cent.
Intestinal deficiency	.. 30 per cent.

Case No. 3.—J. C., a retired *munsif*, contracted diabetes at the age of 37 and is to-day still passing sugar, 4 per cent.; his age is now 75. He is to-day quite hale and hearty, not thin and emaciated, sits as an honorary magistrate, and during my connection with him for 20 years I have never seen him in bed for more than 24 hours, and even then only owing to some minor ailments such as occasional influenza or dengue. He showed no pancreatic deficiency in his stools. The result of stool examination showed the following:—

Pancreatic deficiency	.. 36 per cent.
Intestinal deficiency	.. 28 per cent.

Case No. 4.—Mrs. D., of a very rich zemindar family in Calcutta, contracted diabetes at the age of 46 and was passing sugar, 5 per cent.; to-day her age is 52 and she is still passing sugar, 5 per cent.; she is very fat and a widow, following strictly the obligations of a Hindu widow. Her stool on examination showed the following result:—

Pancreatic deficiency	.. 30 per cent.
Intestinal deficiency	.. 38 per cent.

She was given insulin with strict regulation of the diet as far as possible under the conditions, present, but her urinary sugar never came below 3 per cent. She was then treated with codeine and uranium nitrate and her sugar came down to 0.8 per cent., but albumin appeared in the urine, when all treatment was discontinued, and only lately her urine was examined and 5 per cent. of sugar was found. Her stool recorded exactly the same figure as on the previous occasion.

This is a very instructive case; it shows practically normal pancreatic sufficiency and in spite of a course of insulin there was no appreciable benefit; I will deal with this point later on.

Case No. 5.—D. S., medical practitioner, contracted diabetes at the age of 37 and is still passing sugar, his age being now 48; he has shown 3 to 5 per cent. of sugar all through. He is fat, well built and maintains his health just as well as he was before passing sugar.

Pancreatic deficiency	.. 36 per cent.
Intestinal deficiency	.. 48 per cent.

He was a voracious eater and he can still eat a hearty meal and can also digest as well; yet the sugar in the urine never rose above the level of 5 per cent.

Case No. 6.—Rai Bahadur M., a high government official, with extensive touring duties contracted diabetes at the age of 34; his age is now 53; the first time his urine was examined, it showed nearly 7 per cent. of sugar, he was at one time very bad with carbuncle but his sugar never came down below 2 per cent. He was very susceptible to boils and carbuncles and therefore he was advised insulin treatment. He consulted me and I advised him to have his stool examined. His stool examination gave the following results:—

Pancreatic deficiency	.. 27 per cent.
Intestinal deficiency	.. 40 per cent.

Under these circumstances, I doubted very much whether insulin would do him any good. But he still took insulin with the usual precautions—nearly 1,000 units—yet his sugar in the urine never came down below 2 per cent. Last time I examined his urine, it showed 3.3 per cent. of sugar.

This case is an example of out-door life with an almost European diet for nearly 30 years. He is a very healthy and stoutly built person, digests his food well and still maintains very good general health. Yet in his case insulin treatment was not at all successful. He finally left off the treatment, being tired of so many injections.

Case No. 7.—A lady of high rank, a diabetic for three years, aged 45, passing sugar, 5 per cent., had a course of insulin treatment of 500 units; yet continued to pass sugar in the urine, 4.2 per cent. She was tired of the injections, but being an educated woman wanted to know why the insulin treatment was not doing her any good. She consulted me about it and I advised an examination of the stool to determine whether she was really a pancreatic case. I examined her stool and found the following result:—

Pancreatic deficiency	.. 32 per cent.
Intestinal deficiency	.. 40 per cent.

I definitely told her that insulin would not prove of much avail; it happened that she continued with insulin up to 1,000 units and when her urine came to me for examination it still showed 5 per cent. of sugar to her disappointment. She has since discontinued insulin treatment.

I might cite numerous other cases, but these are quite sufficient for this group.

Now I come to the third group of cases:—

Group III. Diabetes with pancreatic deficiency.

Case No. 1.—P. H., aged 16, complained of thirst, polyuria and hunger, and was very emaciated and anæmic; duration of illness nearly a year; I examined his urine and blood and stool; his urine showed 8 per cent. of sugar; his blood sugar was 0.43 per cent.; his stool showed the following result:—

Pancreatic deficiency	.. 76 per cent.
Intestinal deficiency	.. 66 per cent.

This is a typical case of pancreatic diabetes; he was given 500 units of insulin with a slightly modified diet, mainly substituting *channa* (milk curd) for half the amount of carbohydrate. He was completely freed from sugar in his urine, his blood sugar came down to 0.12 per cent. and he gained about 8 lbs. in weight in the course of three months. When I last saw him about a month ago he was still free from sugar on his ordinary diet.

Case No. 2.—K. C. D., aged about 30, had contracted diabetes only three months before and had lost about 25 lbs. of weight; when he was last seen by me his urine showed 5 per cent. of sugar; he was very dyspeptic, thin and emaciated and anæmic. His stool showed the following result:—

Pancreatic deficiency	.. 58 per cent.
Intestinal deficiency	.. 56 per cent.

He was put on insulin treatment and, in the course of a month, the sugar in the urine has come down to 0.2 per cent.; he has gained 4 lbs. in weight and his anæmic appearance is much better.

Case No. 3.—Mrs. B., aged 34, formerly very stout when I used to see her before as her family physician, was much reduced and had an anæmic appearance; her urine showed 4 per cent. of sugar; her stool showed the following result:—

Pancreatic deficiency	.. 52 per cent.
Intestinal deficiency	.. 66 per cent.

She was put on insulin treatment and she has also improved considerably. Her urine now shows only 0.4 per cent. of sugar and her anæmic appearance has also improved, and I am of opinion that she has also gained in health and weight, though there was no opportunity to take her weight before and after the treatment as she is a purdah lady.

Case No. 4.—J. C., gave a history of diabetes of six months' duration; very thin and emaciated and almost bed-ridden. His urine showed 5 per cent. of sugar; very dyspeptic and had never a good robust constitution. His stool showed the following result:—

Pancreatic deficiency	.. 80 per cent.
Intestinal deficiency	.. 70 per cent.

His is a very difficult case, as although he was put on to insulin treatment with strict diet regulation, yet he is not improving very much. After 100 units of insulin his urine still shows 3 per cent. of sugar.

From the above I draw the following conclusions:—

1. With very marked pancreatic defect, even with a big tumour at the head of the pancreas, sugar was never detected in the urine in some cases.

2. Even with marked diabetes, pancreatic defect could not be found in some cases. Such patients are long lived, keeping good health throughout. None of them responded satisfactorily to insulin.

3. With pancreatic defect and glycosuria, the patients were always in bad health and there was evidence of rapid emaciation from the beginning; these are the cases that respond to insulin treatment.

With the first series of cases it may be concluded that at least some portion of the islets of Langerhans was spared and, therefore, the internal secretion was maintained at a sufficient level to prevent diabetes or glycosuria, whereas in the third series of cases the islets of Langerhans were either inactive or became suddenly functionless, and hence the result is diabetes. Naturally, therefore, the conclusion is that the selection of cases for insulin treatment should be made by determining the activity of the pancreatic function, and the success of the treatment will depend upon this. The many failures of insulin treatment that we see in India—particularly in Bengal—are not the fault of the insulin but of faulty selection of cases. For diabetes is not the result of defect in the pancreas only; it may be so in one group of cases; but there are other factors to be taken into consideration, such as (1) Diabetes resulting from dyspepsia with a high threshold level of the kidney, causing a constant sugar reserve in the blood. (2) Diabetes resulting from the defect in the endocrine system such as defect in the adrenals, thyroid, pituitary and so on. (3) Diabetes arising from shock to the central nervous system such as by heat-stroke or disease or hæmorrhage in the floor of the fourth ventricle. (4) Diabetes from defect in the sympathetic system. (5) Diabetes from excessive metabolism of carbohydrates such as Von Noorden's "excessive mobilisation" or McCay's "onward march." (6) Finally diabetes resulting from liver deficiency—Pavy's "low formation of glycogen from blood sugar," or Claude Bernard's "excessive re-formation of sugar from breaking down of glycogen." I do not want to go into a detailed discussion of those various theories, but what I want to point out is that these cases will never be benefited by insulin treatment; what may happen is that insulin—having glycolytic properties on the sugar—may cause a small amount of glycolysis of sugar in the blood, but that only to a very small extent,

and that also, if at all, only after a very prolonged course of treatment. It is not my intention to discourage insulin treatment, far from it, but rather on the contrary to encourage it by selection of proper cases, so that unnecessary blame is not attributed to one of the most scientific treatments ever discovered.

The question arises as to how to select cases of diabetes due to pancreatic deficiency. The following points may serve as a guide:—

Clinically, the disease is of short duration and within a very short time—say, three months—the patient becomes very emaciated: the anaemia is very marked; the body fat is markedly reduced, leaving a skeleton-like appearance; dyspepsia is very troublesome; sleep at night is disturbed, sometimes there is no sleep during the whole night; weakness is very marked; irritability of the temper is very prominent and there is general lethargy and lassitude.

Pathologically, the pancreatic deficiency as shewn by Cammidge's test is very marked.

Treatment with insulin in these cases is very successful, and by suitable doses complete arrest of the malady may be expected. But the treatment has to be continued on and off periodically for if it is stopped for any length of time, diabetes again appears and with a virulence which sometimes becomes fatal. It is similar to the case of cretinism, where the thyroid treatment has to be continued throughout life or until the thyroid becomes active. So it is with this type of diabetes; there has been complete or partial atrophy of the islands of Langerhans and until there is new growth or recovery of the islands the treatment is to be continued at regular intervals. If the islands are totally atrophied, the treatment has to be kept up throughout the whole period of life.

A Note on the method of determining Pancreatic Deficiency.

The stools of the patient are collected for 24 hours. They are well mixed and then the test may be done by either the dry or the wet method. I myself prefer the wet method. About 5 or 6 grammes of stool are weighed out and extracted with ether by constant shaking for about 10 minutes. The whole of the ether is filtered through a fat-free filter paper. If fat-free filter paper is not available, dip some filter papers into ether, and before the time of use wash them again with ether and they will be fat-free. The ether is collected in a weighed porcelain basin and dried on a water-bath. This again is dried in a dry oven for 2 hours. The result will be fatty acid and neutral fat or non-saponified fat. Another sample of stool, say about 5 or 6 grms., is weighed and boiled with 10 per cent. hydrochloric acid for 4 hours in a flask with a condenser tube. The faeces thus treated are then filtered and then extracted with ether in a Soxhlet's apparatus. The ether is then filtered and evaporated on a water-bath in a weighed capsule or flask. This is again dried in a dry oven for 2 hours. This gives the total fat; from this the previous estimate of the non-saponified fat is subtracted and the result is the amount of saponified fat. The non-saponified fat obtained is again boiled with 5 c.c. of N/10 caustic soda to which a drop of phenolphthalein is added. The boiling is to be done for at least an hour, all the while keeping the quantity of water nearly the same by addition of more water during the process of boiling.

In this way the fatty acid combines with the caustic soda and the excess is treated with N/10 HCl. This gives the fatty acids. From the non-saponified fat the amount of fatty acid is subtracted, and this gives the neutral fat. The following is the relationship showing the intestinal and pancreatic activity:—

The ratio of saponified fat to non-saponified fat gives an index of the intestinal activity. This ratio of saponified fat plus fatty acid to neutral fat gives an index of pancreatic activity.

A Mirror of Hospital Practice.

A CASE OF ABDOMINAL INJURY.

By Y. S. ROW, L.M.P., Bellary.

WHILST I was in an outlying dispensary in this district, a boy of 7 years was brought to me at 11 p.m. on the 14th January, 1923 from a distance of 12 miles with a history of having been injured in the abdomen by the horn of a bull about 4 p.m. that afternoon. The intestines were protruding through a wound in the abdominal wall, and had been wrapped in a dirty cloth tied round his abdomen. His pulse was very feeble and almost imperceptible, with a sub-normal temperature and a cold and clammy sweat all over the body; whilst extreme thirst was present, and all the symptoms of profound shock.

On removing the dirty cloth, about 7 feet of small intestine was found protruding through a small punctured wound $1\frac{1}{2}$ inches to the right of the umbilicus. The patient was now anaesthetised and the protruding gut well washed with warm saline and an attempt made at its reduction. This proved to be impossible, as the wound in the abdominal wall was valvular in character. The wound was therefore enlarged and the gut further examined in order to make sure that it was uninjured. The patient passed urine on the table, soiling the protruding gut, which was then again well cleansed. The gut was returned to the abdomen, and the wound closed, a pint of saline being given hypodermically to combat shock.

The patient's condition was critical for the next 48 hours, but with the exception of a stitch abscess, he made an excellent recovery subsequently. When seen $5\frac{1}{2}$ months later he was in excellent health, and no ventral hernia had developed. The interesting features of the case are the absence of injury to the gut, and the patient's recovery after the protruding gut had been wrapped for some seven hours in a filthy cloth.

TWO CASES TREATED WITH INTRAVENOUS IODINE.

By RAM PERSHAD, L.M.P.,

Chuckmeshi Dispensary, Ranitola P. O., Durbhanga.

I HAVE recently had two cases where it appeared to me that intravenous injections of

tincture of iodine saved either the lives, or the limbs of the patients concerned.

The first was a male adult patient admitted to hospital with acute cellulitis of the whole of the leg and threatening gangrene, as the result of a septic pin prick some days previously. I operated on the case, making free incisions, but despite all surgical measures and removal of all slough, and free drainage, the patient's condition became critical, and gangrene threatened. I put him on to intravenous injections on alternate days, each of 5 minims of tincture of iodine in half a drachm of water. From the time of the third injection, improvement was immediate and rapid, and he made a sound recovery.

The second was a case of acute carbuncle of the leg with severe inflammation of the leg from ankle to knee. After operation the patient did badly, and there was no improvement. I adopted the same procedure as in the first case, giving 5 minims of tincture of iodine in half a drachm of water intravenously every alternate day. Improvement was immediate and marked, and he has made a good recovery.

The method appears to be especially useful in all cases of acute septic infection.

A CASE OF MUSCULAR DYSTROPHY: PSEUDO-HYPERTROPHIC TYPE.

By J. B. HANCE, O.B.E., M.B., B.Ch. (Cantab.), F.R.C.S.E.,
MAJOR, I.M.S.,

Civil Surgeon, Dera Ismail Khan.

THIS case is recorded as illustrating the commonest form of that rare group of diseases, the myopathies, or muscular dystrophies.

and characterised by progressive muscular wasting and weakness during infancy and childhood." (1)

The patient, a young Wazir Pathan, aged about 8, was brought to hospital with the history of 4 years' difficulty in walking, with frequent falls when walking or standing. On enquiry, his maternal uncle was said to have died in early life from a disease with similar symptoms.

The patient's childhood had been apparently normal, until about the age of 4, when it was noticed that his arms were losing power and his gait becoming peculiar.

His previous history afforded no help, the patient having always been healthy.

On examination the most pronounced feature was the disproportionate size of the muscles of the calf, as compared to the wasted, insignificant thighs and upper limbs, well seen in Figs. 1, 2 and 3. Fig. 1 illustrates well the pseudo-hypertrophy of these muscles and the lordosis characteristic of this group of diseases, as well as the characteristic attitude assumed standing with the feet wide apart.

Fig. 2 shows the atrophy of the pectoralis major (compare that of the normal child in Fig. 7). The calf hypertrophy is also well seen.

Fig. 3 illustrates the "winging" of the scapulae consequent on the wasting of the serrati magni and rhomboids and the pseudo-hypertrophy of the infra-spinatus is also well shown.

Figs. 4 and 5 illustrate Gower's pathognomic sign. In rising from the ground patient first rolled over into the quadrupedal position (Fig. 4) and then "climbed up himself" (Fig. 5).

Fig. 1.

Fig. 2.

Fig. 3.

The common feature of these diseases is the "atrophy of the skeletal muscles from congenital defect and subsequent pathological change, unassociated with any lesion of the nervous system,

The weakness of the muscles of the shoulder girdle is well seen in Fig. 6, illustrating the "slipping through the hands" when patient is lifted with the hands of the lifter in his axillæ.

Compare this with the similar lifting of a normal child of the same age. (Fig. 7.)

It is unfortunate that the photograph illustrating the clumsy waddling gait with the feet wide

It was noticed that the patient fell frequently when walking and even when standing for some time in the same position.

The morbid anatomy of this group of diseases,

Fig. 4.

Fig. 5.

Fig. 6.

apart was unsuccessful, but the latter feature of the gait is well seen in Fig. 3, while the relative weakness of the shoulder and upper arm muscles as compared to those of the forearm and hand is

Fig. 7.

well-illustrated in Figs. 2, 3 and 4, as are the relatively insignificant buttocks and thighs.

Examination.—With the exception of the above noted changes in the muscular system, no abnormality could be detected in the cardio-vascular, respiratory, digestive, urinary and nervous systems. The reflexes were unaltered, sensations unchanged, and sphincters unaffected. General health was good and appetite and spirits unimpaired.

constituting it will be remembered, an atrophy of the muscle fibres combined with increase of nuclei beneath the sarcolemma and deposit of fat between the muscle fibres, and the unknown aetiology constitute an interesting study.

Whether the recent modification of our previous ideas as to the innervation of the skeletal muscles will afford any clue to the causation and treatment of these diseases is an equally interesting speculation.

A CASE OF VESICAL CALCULUS FORMED AROUND AN INSERTED FOREIGN BODY.

By Dr. J. W. McK. NICHOLL, M.D. (Cantab.),
C. M. S. Hospital, Quetta.

B. K. was admitted to this hospital on 30th April, 1924, suffering from the typical symptoms of vesical calculus; he gave the following interesting history. Six months previously he had had an attack of renal colic, which was relieved by some subcutaneous injections, but retention of urine followed; a medical practitioner then passed a rubber catheter and withdrew the urine; he then filled and washed out the bladder with a solution of potassium permanganate, but this fluid did not return. After twisting the catheter about he withdrew it, saying he could do no more. The patient passed the solution mixed with urine but in small quantities frequently and a burning sensation was felt in the penis. For two months the patient passed pus mixed

with blood, before, during, and after micturition; at the end of the act too, small pieces of "flesh" were passed. These symptoms he stated cleared up on his taking some medicine by mouth.

On admission he complained of a burning sensation during micturition and pain in the hypogastrium while walking.

The day after admission a lithotrite was passed and the stone crushed. Among the debris evacuated from the bladder were pieces of rubber catheter; these were embedded in the centre of the stone. The stone was of soft subsistancy, yellow in colour and oxalic in origin.

Undoubtedly, the doctor had used a rubber catheter which had perished, the tip had broken off in the bladder, around this the stone had formed. The patient made an uneventful recovery and was discharged on the fifth day.

The purport of this note is to utter a warning against the use of "perished" rubber catheters and also to show how quickly a stone forms around a foreign body in the bladder.

NOTES ON A LARGE SCROTAL HERNIA OPERATED UPON UNDER APOTHE-SINE.

By S. G. CHAVAN,
CAPTAIN, I.M.S. (T.C.)
and

J. P. ARLAND,
LIEUT., I.M.S. (T.C.)

Indian Station Hospital, Kirkee.

A MADRASI by name Michael, aged 65, by occupation a *chowkidar*, was admitted into the Cantonment Hospital, Kirkee, with a large scrotal hernia.

Previous History. The patient stated that he noticed a protrusion into the left half of his scrotum two years ago. He was subject to chronic bronchitis, which aggravated the condition of the swelling. The tumour was at first the size of a small lime and was easily reducible. During paroxysms of coughing the protrusion gradually increased in size, much to the patient's discomfort.

We first saw him on 29th September, 1924. The hernia was the size of an orange and reducible. The man was not willing to undergo an operation. He was discharged the next day.

On 6th December, 1924, the patient again sought admission. He came in with a very severe attack of bronchial asthma. The hernia had very appreciably increased. A little difficulty was experienced in effecting its reduction. He again expressed unwillingness to be operated upon. A truss was applied and the patient discharged.

On 2nd February, 1925, the patient was brought into hospital in a state of collapse with

a pulse of 115 and a subnormal temperature. He was suffering from an acute attack of bronchial asthma. Examination disclosed an enlarged heart, emphysematous lungs, and rigid tube-like arteries. The hernia had assumed the dimensions of a large cocoanut. It was irreducible. There was an impulse on coughing. The scrotum was distended and tense. Enlarged vessels were seen making a free anastomosis around the lower abdominal wall.

Operation was decided upon, to which the patient now readily consented. Local anaesthesia was used. Apothesine (Parke Davis) was chosen. A 0.5 per cent. solution was used.

Technique of Anaesthesia. A point 1 inch internal to and $\frac{1}{2}$ inch below the anterior superior spine was selected and an intradermal wheal made. The needle of the hypodermic syringe was plunged vertically down till the resistance of the external oblique was felt and four drachms of a 0.5 per cent. solution deposited. The needle was then thrust horizontally in a direction midway between the anterior superior spine and the spine of the pubis and one ounce injected. The needle was withdrawn and an intracutaneous infiltration made in the line of the proposed incision. After exposure of the sac its neck was infiltrated with about 2 drachms.

Operation. An incision $4\frac{1}{2}$ inches long was made parallel to Poupart's ligament, and extending to the upper third of the scrotal bag. A finger was passed into the scrotum, adhesions broken down and the gubernaculum testis severed. The external oblique aponeurosis was found firmly united to the sac. There were a number of adhesions between the sac and the internal oblique and transversalis muscles, which were broken down. The cremaster was completely atrophied. The abdominal rings were unduly stretched and large, and admitted five fingers. At this stage taxis was tried and the contents of the sac reduced. The cord with the attached testis was ligatured near the internal abdominal ring and cut away. The sac was transfixed and the internal ring completely closed. The anterior sheath of the rectus was incised, thus mobilising the internal oblique, which was stitched along with its conjoined tendon and tucked under Poupart's ligament. The aponeurotic flaps of the external oblique were sutured by the Andrews Halstead method. The skin wound was incompletely closed and a gauze drain placed at the bottom of the scrotum.

On 7th March, 1925, the patient was discharged completely cured.

Observations.—

- (1) The anaesthesia was perfect and profound.
- (2) Absence of shock.

(3) Strength to the weak abdominal wall was given by completely obliterating the canal, for which reason the cord with the testis was removed.

(4) Incision into the rectus renders easy the mobilising of the rectus internal oblique.

(5) Large quantities of apothesine were purposely used, as much as 13 grains were spent and no toxic effects noticed.

A CASE OF ANKYLOSIS OF THE KNEE-JOINT CURED BY EXCISION.

By U. N. RAY CHAUDHURI, L.M.S. (Cal.),
Teacher of Surgery, Campbell Medical School and
Surgeon to the Hospital.

IN his interesting article in the *Indian Medical Gazette* of December last, Major W. L. Harnett, F.R.C.S., I.M.S., mentioned a case of ankylosis of the knee-joint following septic arthritis. He gave a photograph and also a radiographic picture of the knee, shewing what extreme deformities one has to deal with at times. Excisions of knee-joints are not of every day occurrence, and the results of excisions in such cases when performed—in my opinion—should be fully reported to enable the general practitioner to form an estimate of what may be expected from conservative methods. Unnecessary amputations in such cases may thus be avoided. This patient is a native of Dhubri, Assam. He is a cultivator by profession and is 24 years of age. He was kicked by a bullock on his right knee while working in the fields six months previous to his admission to hospital. He developed severe septic arthritis. The joint became very much swollen and painful, and being far away from competent medical aid he himself punctured the joint and let out the pus. Violent sepsis followed, resulting in long-continued suppuration with destruction of the end of the femur and backward dislocation of the tibia and fibula. The condyles had separated as sequestra from the end of the bone, which latter stuck out of the wound for months. He was treated in a civil hospital in Assam and the end of the bone in time became covered by dense, rough scar tissue. The patella was displaced to the outer side and lay fixed and buried in dense adhesions. Firm ankylosis followed with the joint flexed at an angle of 120° . There was no movement of the joint in its new position. The skin was extremely rough and in places ulcerated, and could not be got into an ideally healthy condition before operation.

Operation was, however, undertaken, and the joint was excised on the 22nd September, 1924, though the chance of lighting up old sepsis was very great. I carefully isolated the rough, ulcerated skin area by gauze and then by an elliptical incision got down to the lower end of the femur, the lower curve of the ellipse sweeping across the upper edge of the head of the tibia. About 2 in. of the femur was sawn off at right angles to the shaft. The upper end of the tibia was sawn off parallel to the articular cartilage.

The sawn-off surfaces were then gradually brought into apposition by extension and afterwards by light strokes of a mallet. The sharp projection at the posterior edge of the tibia could not be smoothed up, owing to the gross pathological displacements and the proximity of the popliteal vessels in the mass of dense adhesions. The subsequent course of the case shewed that the spur did not exert any injurious pressure over

Fig. 1.—Photograph of patient on admission.

the vessels or the sciatic nerve. The weight-bearing surface of the femur was about $\frac{3}{4}$ in. less than that of the tibia, as I was obliged to go somewhat high up the shaft. The patella was excised, the soft parts stitched up after careful hæmostasis, and the skin united. No drains were put in and the limb was kept on a straight back splint. The stitches were removed on the 8th day, and a week later the limb was encased in plaster of Paris. The plaster was removed after seven weeks on the 23rd November, 1924. Before the plaster casing was finally removed massage was employed from time to time to keep up the tone of the muscles.

The result of the operation has been a synostosis in the most useful position—that of full extension. The shortening is about 3 in., but this has been overcome by a wooden patten with laced leather uppers (like that of a boot). The patient can now easily walk without crutches and

even without the patten, though in the latter case he tilts his pelvis down on the affected side, as

Fig. 2.—Skiagram of the knee-joint before operation.

Fig. 3.—Final Result.

was demonstrated at a clinical meeting of the Calcutta Medical Club on the 26th March, 1925.

Note by Major W. L. Harnett, F.R.C.S., I.M.S.—I saw this case with Dr. Ray Chaudhuri last autumn. The limb was a horrible sight, with two inches of the femur sticking out, covered by unhealthy, ulcerated skin. Amputation looked the only course, but the patient was in good condition, and after weathering such a storm of sepsis it seemed likely that his immunity would be high. So we decided on conservative measures; amputation could always be done later in the event of failure.

The result has fully justified our view, and Dr. Ray Chaudhuri is to be congratulated on the admirable limb which has resulted.

A NOTE ON THE TREATMENT OF TROPICAL ULCER.

By J. F. JAMES,

MAJOR, I.M.S.,

Civil Surgeon, Naga Hills, Kohima.

THE number of names given to this condition serves as an index of its wide-spread nature. It exists in Assam under the name of Naga sore. Its identity is easily established by finding the fusiform bacillus plus the spirochæte with the microscope.

It is generally conceded that its effective treatment is often difficult. This, indeed, is apparent when the list of remedies recommended is reviewed. Formalin, carbolic acid, mercury, chlorinated lime, iodoform, silver preparations, bismuth and others externally; salvarsan, antimony and iodides internally.

I have treated many cases during the last few months with uniform success by means of wet dressings of magnesium sulphate. A thickness of lint or rag of about a quarter of an inch, soaked in a 25 per cent. solution, covered with plantain leaf or oiled paper and a bandage suffices. The sore cleans rapidly and the dressings are continued until healing is complete.

For very foul sloughing cases two or three hot permanganate baths daily are a useful adjunct.

The action of this drug is more than merely osmotic. Common salt for instance is of little use.

Magnesium sulphate has the following advantages:—it is cheap, non-poisonous, simple to use, painless, and in my experience efficacious. Incidentally it will be found useful for a variety of septic conditions.

The wet dressings must be properly applied, the waterproof covering must overlap sufficiently.

This point is stressed for the reason that many practitioners fail to realise that the essence of a wet dressing consists in its remaining wet.

Indian Medical Gazette.

JUNE.

THE MEDICAL EDUCATION CRISIS IN BENGAL.

THE General Council of Medical Registration and Education of the United Kingdom has recently withdrawn its recognition of the medical degrees of the Calcutta University in consequence of the refusal of the University to permit the Inspector of Medical Education to inspect the final examinations of the University. The reason given by the University for the refusal was that "it is not usual to grant permission of this character." The other universities have done everything in their power to comply with the recommendations of the General Medical Council, and even the Calcutta University recognised the right of the Medical Council to examine the teaching institutions, but when it came to the examinations themselves being inspected they refused as a matter of principle. Undoubtedly the University is quite within its rights in refusing outside interference with the examinations, and the only question for decision is whether the General Medical Council is not also within its rights in withdrawing recognition of the degrees. The position of the Council appears to be that it is obliged to satisfy itself as to the standards of the degrees which are recognised; if it is not satisfied the withdrawal of recognition is bound to follow. The Calcutta University takes up the position that the recognition of the degrees is a matter of reciprocity, and that recognition of *degrees* can "never mean inspection either of the colleges or of the examinations held under the auspices of the University." The syndicate of the University also points out that it was never directly informed that the recognition of the degrees depended on inspection of examinations such as is carried out in the case of the examinations in the United Kingdom which have always been inspected by the Council. The Syndicate also believes that the prestige of its examinations will not suffer by the withdrawal of recognition, and that the graduates of the University will be at no disadvantage as compared with those of the recognised Universities of India.

There are sharp differences of opinion on these points and perhaps it is because of the misgivings which are being felt by the prospective graduates that the Syndicate assures

them that the necessary steps are being taken to ensure that the recognition of the degrees will be continued by the General Medical Council. The hard fact at present is that the recognition has been withdrawn, and unless the Privy Council can be moved to force the hands of the General Medical Council, it now becomes a question of restoring the recognition which has been withdrawn, not of continuing an existing recognition.

The Syndicate believes that "until its efforts are finally successful, such students who graduate from the University will still be able to appear at the final examinations of the Conjoint Board of the Royal Colleges of Surgeons and Physicians in England and qualify themselves for practising in England and sitting for the I.M.S. and all the higher medical examinations." This assurance must be very comforting to the young medical men who have feared that their prospects have been seriously compromised by the action of the Calcutta University, but they would be still more relieved if they had the assurance of the authorities of the Royal Colleges of Surgeons and Physicians on the point at issue. They will also feel that it would be desirable to have the assurances of the Governments and local bodies of the other provinces of India that their degrees will be accepted on terms of equality with the degrees of the Universities which are still recognised. There will, in fact, be great anxiety on their part until the doubtful points have been cleared up and until the Calcutta University has taken the promised steps to ensure the recognition of their degrees. It is obviously most unsatisfactory that the graduates of the Calcutta University should, through no fault of their own, be kept outside the great brotherhood of medical graduates of the British Empire. Many of them are inclined to the view that it would have been wiser and more tactful of the University to have followed the same course as the other Universities of India and to have allowed the inspector to see their examinations: the question of the right of the Medical Council to inspect the examinations could have been settled afterwards. If the Syndicate has acted properly and can ensure the continuance of the recognition it will be absolved from blame, but on the other hand if the Medical Council was acting within its rights in demanding the inspection, the disabilities suffered by the students will be regarded as being due to the action of the Syndicate. The Syndicate might very well take up the position that it does not care whether the degrees are recognised or not, and that it desires to escape once for all from the irksome restraints which are involved by outside control. If it takes up this attitude it will only have to obtain the approval of the medical

students of Bengal and there will be nothing more to be said.

The students, however, are by no means likely to agree with this view, they are inclined to say that it is all very well for the existing graduates who already are in possession of all the privileges which result from recognition of their degrees to ride the high horse, their interests are not at stake; but that is no reason for jeopardising the prospects of the coming generation of medical men in Bengal.

Some go so far as to say that if the wise counsels of the lamented Sir Ashutosh Mukherji had still been at our service such an impasse would never have been brought about.

There is no use in crying over spilt milk; what is needed is to rectify the harm that has been done, and it is hoped that the Calcutta University will act in such a way as to protect the interests of their students without regard to legal points which are notoriously liable to prove broken reeds to those who rely on them.

The latest information which is available is that the Committee of the General Medical Council has considered the remonstrance of the Calcutta University, and its request that the recognition of the degree should be continued until November next. The Committee has passed a resolution stating its inability to recognise, for the time being, the medical diplomas of the University of Calcutta as furnishing a sufficient guarantee of the possession of the requisite knowledge and skill for the efficient practice of medicine, surgery and midwifery, but that it would welcome and give most careful consideration to any further information on the subject.

This resolution, while it gives ground for hoping that the Calcutta degrees may again be recognised, is cold comfort to those who are going up for the final examinations during the present year, and it is to be hoped that their unfortunate position will receive the most earnest consideration of the Calcutta University.

It is interesting to note that the Irish Free State has passed through a crisis in some respects similar to that experienced in Bengal, and the solution of the difficulty has just been brought about by the action of the Free State Government which authorises the General Medical Council to exercise authority in respect to medical practitioners in the Irish Free State. The Bill is for the period of one year, but evidently there is greater anxiety on the part of the Free State authorities that their practitioners should continue to enjoy the same privileges as their colleagues in the United Kingdom.

SPECIAL ARTICLE.

THE INSECT MENACE.

ON January 16th, 1925, in connection with the Indian Science Congress held at Benares, a joint meeting was held of the Medical Research, Agricultural, Zoological and Botanical Societies; and a combined discussion took place on the subject of "Insects and their relation to diseases in man, animals and plants."

The discussion was opened by Lieutenant-Colonel F. P. Mackie, O.B.E., M.D., F.R.C.P., F.R.C.P.S., I.M.S., who reviewed our knowledge of the problem as it affects man. His address has already been published in the *Indian Medical Gazette* for April 1925, p. 172.

The following gentlemen continued the discussion from their respective points of view:—

1. T. Bainbrigge Fletcher, M.A., Imperial Entomologist.
2. S. K. Sen, Assistant to the Imperial Entomologist, Veterinary Laboratory, Muktesar.
3. Lieutenant-Colonel S. R. Christophers, C.I.E., I.M.S., Director, Kala-azar Commission, Indian Research Fund Association.
4. E. A. Andrews, Entomologist, Indian Tea Association.
5. J. T. Edwards, Director, Imperial Veterinary Laboratory.
6. P. B. Richards, Entomologist to the Government of the United Provinces.
7. Professor A. Howard, Indore.

Below we publish the verbatim text or abstracts from the speeches at the discussion.

THE IMPORTANCE OF ENTOMOLOGY TO INDIA.

By T. BAINBRIGGE FLETCHER, M.A.,
Imperial Entomologist, Pusa.

To the vast majority of people the fact that insects are small animals is practically equivalent to the idea that they are therefore of small importance. This idea, however, is quickly dispelled by even a small realisation of the numerous ways in which the activities of the insect world affect man and his possessions. Such activities are especially evident in a country such as India, where seven-tenths of the people depend directly for their livelihood on the produce of their fields, which produce is ravaged by insect pests both before and after harvest, and where such a vast aggregate toll is taken by insect-borne disease, both amongst man and his domestic animals.

Limitations of time prevent any detailed statements, but it will be useful to indicate very briefly a few directions in which insects are of importance to us in India.

Agriculture forms the ultimate foundation of the whole wealth and prosperity of the Indian Empire. As the poet puts it:—

"Great is the sword and mighty is the pen,
But greater far the labouring ploughman's blade,
For on its oxen and its husbandmen
An Empire's strength is laid."

Now practically every cultivated plant that is grown in this country is subject to attack by insects throughout the whole period that it is in the ground. Some insects feed openly on the leaves or suck the juices, whilst others lead a concealed existence boring in the buds, leaves, shoots, stem or even in the roots. The damage done is often only evident on close inspection—although occasionally, as in the case of attack by locusts or by swarming caterpillars, it may be highly spectacular—but it is none the less real because it is not very conspicuous or because it is taken as a matter of course by the farmer. It is usually computed, by those who are in the best position to judge, that the annual damage to agricultural crops by insects is about ten per cent.:

that is to say, the farmer who reaps what he considers to be a normal full crop, actually gets only nine-tenths of what he would have got had there been no damage by insect pests. Some four years ago I made a rough calculation, based on the acreage figures of crops and the value of the out-turn, and estimated the annual average value of the out-turn of agricultural crops in India as Rs. 1,682,42,73,000. Applying the ten per cent. rule to this figure, we get an annual loss due to crop pests of one hundred and eight crores in round figures.

It is not only during their period of growth that crops are attacked. After harvest the products, and food grains in particular, are damaged by insects, so much so that elaborate precautions have often to be taken to guard against such losses, which must be enormous in the aggregate throughout the whole country, although it is impossible to state any definite figures, and in the case of food-grains we may include damage under the heading of stored products under the ten per cent. rule applied to the growing crop.

Besides agricultural crops, there are roughly a quarter of a million of square miles of forest in India, of which roughly a half is workable. Omitting the unworkable half altogether and remembering the time that it takes for a forest crop to mature, we shall probably be well within the mark in placing the average annual loss by insect pests at a minimum figure of Rs. 100 per annum per square mile, which gives us another one and a quarter crores to add to our bill against the insect world.

Now we come to the various insects which carry disease to man and animals. Taking the human diseases first, we have those which we know to be wholly insect-borne, such as malaria, plague and elephantiasis; some which we suspect to be carried by insects, such as kala-azar and leprosy; and some which are at least partially spread by insects, such as cholera. Plague, which, as everyone knows nowadays, is carried by rat fleas, carried off a total of 10,254,221 people in the twenty years 1898-1918, or on an annual average of over half a million. The annual deaths from malaria are probably in the neighbourhood of one million, and another hundred thousand may be ascribed to other insect-borne diseases, giving us a total death roll of 1,600,000. It is difficult to put a money-value on this loss, and it must be remembered that the figures given are totals of all degrees and ages in the population and that probably the larger proportion are not wage earners; so that we may estimate a modest value of Rs. 100 per life, which gives us a figure of sixteen crores. The losses to the wage-earning capacity of the people by sickness and disability are also very large but quite incalculable.

Next we have the cattle, on which the whole cultivation of the country depends, and other domesticated animals, whose total money-value may be estimated at Rs. 47,79,50,000; taking the losses in live-stock and animal labour or produce (hides, milk, flesh, eggs, etc.) due to premature death, debility or damage caused by arachnids and insects at 8 per cent. of this total value, we find an annual loss under this head of nearly four crores.

The Army always bulks large in the Indian budget and an army, to be ready for action, must have a certain amount of reserve stores, of which a large proportion is composed of articles subject to attack by insects, such as clothing, blankets, saddlery, etc.—all of which are liable to insect attack—besides provisions and fodder which we have already considered under the heading of stored products. In connection with transport also the Army is directly concerned with such problems as surra and other insect-borne diseases of transport animals. Incidentally I may remark that the most suitable containers for the charges of heavy guns are made of silk, which is of course an insect product, and that lac, which is another insect product, and at present practically a monopoly of India, was very

extensively used during the great War as a varnish for the interior of shells.

Most of you have come to this Congress by rail and have passed over railway lines which are laid on wooden sleepers, whose upkeep and renewal forms a very appreciable factor in railway finance. Nowadays most of these sleepers are treated to prevent attack by termites (the so-called "white ants") which in many localities will destroy untreated sleepers in the course of a few months. Some fifteen years ago certain Indian railways imported very large numbers of sleepers made of Australian wood which were reported to be immune to attack by termites in Australia. Be this latter fact as it may, it is very certain that the Indian termites had no such dislike, but positively revelled in the bountiful feast of Australian wood so kindly provided for them. The idea that more than one kind of termite was concerned and that wood which was immune to termites in one locality would not necessarily be immune in another locality to termites of quite different species and tastes, was one which apparently did not occur to the railway officials concerned; but had expert entomological opinion been taken in the first place, it is more than probable that the heavy losses which were actually incurred would have been avoided.

It is impossible to mention even briefly all the ways in which insects affect our everyday life, but such are a few of the directions in which damage by insects affects the welfare of the State. Totalling the figures for insect damage to crops, stored products, and forests, and due to insect-borne diseases of man and animals, we reach a figure of at least two hundred crores of rupees which are annually lost to the resources of this country through insect pests.

Now you may ask, what are we doing about it? What steps is Government taking to prevent or lessen this enormous wastage of the national wealth? And it must be admitted in answer that the steps which are being taken are quite inadequate to the magnitude of the problem concerned. At present the Government maintains twelve entomologists for the whole of India; and in addition there is one—not in Government employ—maintained by the Indian Tea Association. Of this total of thirteen, six are employed under Agricultural Departments, two at the Forest Research Institute, four under the Medical Department, and one in the Zoological Survey. Further, these thirteen men are stationed in nine different places, which means that they require nine separate laboratories, libraries, collections, staffs, etc. Hence there is no co-ordination of work and there is considerable waste of funds and effort. What is required, in my opinion, is a centralisation of work and staffs, at least so far as research work is concerned, in order that a strong co-ordinated central staff, dealing with both pure and applied problems, may be in the best position to turn out work which will be at once a credit and a benefit to the country as a whole. Such a scheme for a Central Entomological Institute, staffed by an Indian Entomological Service, has already been submitted to and approved of by Government, but has been shelved indefinitely on the ground of financial stringency. If, however, there is such financial stringency, it would seem to be truer economy to make a really serious attempt to check the present enormous wastage of the national wealth of India caused by insect pests; and if we, by a study of insects and by practical application of the knowledge gained thereby, can save even one per cent. of the present losses, such a saving would more than justify the most complete expansion of entomological work that we can possibly imagine.

INSECTS AND THEIR RELATION TO THE DISEASES OF MAN, ANIMALS AND PLANTS.

By S. K. SEN.

Assistant to the Imperial Entomologist.

ALTHOUGH it is customary to accord the insect pests of domesticated animals a subordinate position as

compared with those of man and plants, the entomological aspects of an animal pathology in India raises itself to a position of paramount importance by reason of the fact that in India agriculture and hence the very livelihood of the people depends on cattle. But whilst medical entomology has made rapid strides during recent years, and has now placed itself on a footing where it can assure itself of a future fraught with great possibilities, very little appears to be on record to bear evidence of any organized efforts having been made in India to elucidate the aetiology of even the most important diseases of live-stock, in the propagation of which arthropod vectors are likely to be concerned.

It is not possible to present, within the small compass of this abstract, a resumé of the present position with regard to all the diseases which are or may be transmitted by arthropods, and in what follows an attempt is made to indicate the present position with regard to the important diseases only:—

(a) Diseases due to protozoal parasites:

(1) *Surra*.—The causative organism, *Trypanosoma evansi*, has been proved to be mechanically conveyed by *Tabanus striatus* (Mitzmain; Shilston and Patel, 1919) and by various other species of *Tabanus*, notably *T. albemidius* (Cross and Abdulla Khan, 1921). In 1921 Cross and Patel published results to prove that the disease was cyclically transmitted by the tick, *Ornithodoros crossi*, Brumpt, but Yorke and Macfie (1924), in Liverpool, repeated the experiments with infected ticks, with negative results.

(2) *Piroplasmoses*.—In another paper presented to this Congress ("The Piroplasmoses of Cattle in India: A Preliminary Note") reference has been made to the fact that an examination of about three to four thousand blood smears at the Muktesar Laboratory during the last two years has revealed that infection with *Babesia bigemina*, the causative organism of Texas cattle fever (the so-called "red-water"), which is conveyed by ticks, is extremely widespread in India and that infection with *Theileria mutans* is almost as common; and since *T. mutans* is morphologically almost indistinguishable from *T. parva*, the causative organism of East African Coast fever (also conveyed by ticks), the subject of ticks merits considerable attention in India.

(3) Amongst other diseases of animals in India—although comparatively of minor importance—reference may be made to canine piroplasmosis (the so-called "malignant jaundice") of dogs, transmitted by the tick, *Rhipicephalus sanguineus*; to canine leishmaniasis, supposed by some to be conveyed by the flea, *Ctenocephalus canis* (although this possibility has been very recently discredited by Nicolle and Anderson); to spirochaetosis of fowls, conveyed by the tick, *Angas persicus*; and to pigeon malaria caused by *Hamoproteus columba* which has been shown to undergo its developmental cycle in the dipterous insect, *Lynchia maura*. Reference may also be made to the trypanosomiasis of sheep, in which the causative organism undergoes its developmental cycle in the sheep-ked, *Metophagus ovinus*, the infection occurring, as has been very recently (1924) shown by Hoare, *per os*.

(b) Diseases due to filterable viruses. *Rinderpest*.—Except for a few inconclusive experiments carried out by Curasson (1922) in Poland with certain species of ticks and *Tabanus*, little appears to have been done to test the possibility of arthropods acting as vectors of rinderpest. During the last two years, however, a long series of attempts has been made at Muktesar to transmit the disease by means of *Aedes* (*Stegomyia*) *albopictus*, *Musca domestica* and *Linognathus vituli*, but the results have been negative. These experiments form the subject of a more detailed communication presented to this Congress.

(c) Diseases due to bacterial organisms.—As is well known, with the notable exception of *Bacillus pestis* which, for the purpose of multiplication, usually chooses

the special cultural medium furnished by the stomach of the flea, *Xenopsylla cheopis*, bacterial organisms are not generally adapted to any highly specialized environmental conditions, so that the same species of bacterium may be amenable to conveyance by widely different species of arthropods. In a country extremely rich in insect fauna, such as India, the possible role played by various species of flies in the transmission of such diseases, as anthrax, becomes, therefore, a matter of serious import, particularly in view of the findings of Mitzmain (1914) and Morris (1918) which prove that the disease is capable of being mechanically transmitted by several species of both biting and non-biting flies, almost all of which are of common occurrence in India. At the same time, the presence of a close morphological similarity between the hæmorrhagic septicæmia organisms and the plague bacillus is of obvious significance as to the probable character of the invertebrate host, if any, involved in the propagation of the former disease.

(d) Diseases due to metazoan parasites.—Considerable advance has been made during recent years in our knowledge regarding diseases caused by the grosser parasites. As examples of diseases almost exclusively confined to animals, and in which arthropod vectors are concerned, mention may be made of cestriasis caused by "bots" in the stomachs of equines, "warbles" produced by various species of *Hypoderma*, "lousiness" caused by Mallophaga, and equine habronemiasis transmitted by *Stomoxys* and *Musca*; the last-named condition—which has been dealt with at greater length in another paper presented to this Congress—is of considerable interest to India at the present moment, in view of the possibility that the so-called "bursati" of India may prove to be, in reality, a form of cutaneous habronemiasis, variously known in other countries as "summer sores," "esponja," etc.

Whilst agricultural entomology is of little immediate concern to the veterinarian except in so far as it relates to the insect pests of fodder, the results of far-reaching significance already achieved in the domain of medical entomology, through the classical researches of such men as Manson, Ross, Breinl, Noguchi and Bacot, must continue to be the main source to which veterinary workers must turn now and again for analogy and for guidance as to the manner in which investigations upon the entomological aspects of animal pathology may be pursued with profit. There is a growing recognition of the essential solidarity of pathological entomology and of the necessity of intimate co-operation amongst the units engaged in investigation upon its various aspects. As an example of a disease of immediate concern to India, the investigation of which calls for the active co-operation of both the medical and the veterinary departments, mention may be made of canine leishmaniasis in relation to human kala-azar. Reference may also be made to the investigations that are in progress at Puri (Orissa) upon the relationship of human filariasis to the various forms of filarial affection of animals; whilst a number of diseases could be named (such as anthrax and myiasis) which are capable of being produced both in man and animals through the agency of the same species of insects; and, finally, the question of resistant animal hosts functioning as reservoirs of viruses continues to be a subject of surpassing interest for the medical and the veterinary worker alike.

In conclusion, it may be pertinent to remark by way of general observation that, in view of the great uncertainty that frequently attaches itself to the question of the exact specific identity of the lower organisms, the occurrence in the alimentary tracts or the tissues of insects, of parasitic bodies suspected to be the developmental forms of known pathogenic organisms, can only be of very limited value as a factor in the elucidation of the aetiology of a disease, and the verdict as to the complicity of any species of insect in the propagation of a disease must depend on the extent to

which the actual production of the disease may be effected by means of transmission experiments. In this connection the immediate desideratum would appear to be the standardization of the technique employed in transmission work, as experience has shown that the various methods of experimentation advocated are frequently very crude and, at times, extremely laborious. During the last two years, at Muktesar, critical experiments have been carried out with a view to deciding upon the comparative merits of the various methods recommended, and efforts have been made to evolve a technique suitable for use in transmission experiments with mosquitoes and non-biting flies.

MAN, ANOPHELES AND THE MALARIA PARASITE IN RELATION TO THE FAUNAS.

By S. R. CHRISTOPHERS, C.I.E., O.B.E.

LIEUT.-COLONEL, I.M.S.

ONE of the most remarkable facts in connection with animal life on the globe is the existence of the zoogeographical realms, or as one may prefer to express it, of the faunas. To the systematic zoologist the world faunas are so obvious a fact that he seems often to take them for granted, leaving the explanation of their existence to the future. The medical man goes further and ignores them altogether. I have recently been much puzzled to know whether anthropologists also prefer to ignore these natural kingdoms that have their boundaries almost as precisely set as any political state; it is certainly difficult to find in most recent writings any reference to the distribution of man from the stand-point of that of animals, a relic perhaps of the day when man was considered as above and apart from the rest of creation.

In the malarial cycle we have three distinct animals concerned, man, anopheles and the malaria parasite. It would be remarkable if faunal relationships did not enter into the cycle somewhere. Before going further perhaps it would be well to refer with the greatest briefness and in very general terms to the main features of the existing world faunas.

Extending over most of Europe, Asia and North America is the vast Holarctic realm representing apparently the newest order of life on the globe, divisible into the Nearctic or New World region, and the Palearctic or Old World portion. Occupying South and Central America is the old and isolated Neotropical realm, and in the tropical Old World the Ethiopian and Oriental regions, which together might be termed the Paletropical realm. In many respects a very distinct region lying between the Palearctic and the Paletropical is the Mediterranean region, embracing North Africa, the south of Europe and a tract of country extending far to the east of the present Mediterranean Sea. There remains the Australasian realm, recognised the oldest and longest isolated of all the realms. The limits of these regions and realms are too well known to require treatment here. I need only emphasize the fact that they are thoroughly well known to systematic zoologists, who largely think in terms of their faunas, and point out how far the trio of forms now under discussion, man, anopheles and the malaria parasite, appear to conform to them.

The working out of the distribution of the species of Anopheles has shown that this tribe or genus exhibits in a high degree what may be called typical faunal relationship. No special Anopheles fauna can as yet be ascribed to the true Australasian realm. It is true certain species are special to it, but they are almost certainly a later extension, just as Australian man can scarcely be in any way connected with the original isolation that preserved the marsupial mammalian fauna. A neotropical Anopheles fauna is, however, very obvious. Of the sub-genera into which recent work has divided the Anopheles, one is entirely confined to South and Central America, another is not

represented at all, whilst the third occurs in a special form in this area. The Palearctic region is largely characterised by a paucity of species; either the sub-genus *Myzomyia* has never penetrated so far, or it has been eliminated, possibly by climatic changes. The paletropical realm is characterised on the other hand by a great development of the sub-genus *Myzomyia*, which appears to be the most modern form of the genus *Anopheles*. From the point of view of the distribution of *Anopheles* this realm is divisible into (a) Mediterranean, (b) Ethiopian, (c) Oriental, and (d) an Australasian extension. These areas are as a rule represented by distinct but nearly related forms. Thus in the case of a particular group of *Myzomyia* the Mediterranean region has *A. hispaniola*, *A. multicolor* and *A. superpictus*; the Ethiopian region, *A. cinereus*, *A. transvaalensis* and others; the Oriental realm, *A. turkhudi*. Nevertheless there are some general features characteristic of the different regions, the group *Neocellia* being especially developed in the Oriental region, whilst *Cellia* and *Myzomyia* in the restricted sense are specially developed in the Ethiopian and Mediterranean; the annules group is Australasian.

Anopheles then conform very markedly, indeed, to the general character of the distribution of animals as worked out mainly in regard to the mammals. We may regard the appropriate groups of *Anopheles* as integral portions of the great world faunas.

Coming to the relationship of man to the faunas, I am at a disadvantage in that the study of man is a highly specialised subject and one on which I must speak with great diffidence. Were the facts, however, regarding the distribution of man presented to a naturalist in the rough, I do not see how he could fail here also to recognise a close adherence to the general plan of the great zoogeographical areas. Presumably there is no Australasian man in the true sense of his presence in Australasia; as in the instance of *Anopheles*, man must here represent a recent extension into this area, though possibly relatively ancient in respect to the history of man. Also it seems almost certain that there is no true Neotropical man. Representative of the Paletropical subdivisions, however, there appear to be certain distinct forms of man as follows: (a) Ethiopian, Negro and Negrito; (b) Mediterranean, Hamitic and Semitic races; (c) Secondary Australasian, Australian and Tasmanian man. In respect of Oriental man there would seem to be a nice question at issue as to whether this region is truly represented or not. Probably, if represented at all, it is a late stage in this fauna with which man is connected, not the fundamental groundwork.

The great bulk of the human race, apart from the African type, would appear to be Holarctic, if not purely Palearctic; viz., Caucasian and Mongolian man. These races, like the Palearctic fauna in general, would appear to be rapidly extending and to have largely populated the Oriental region. I am here, however, on ground where I have not the necessary qualification of knowledge to guide me. That the relation of man to the faunas has not been more expressly dealt with seems, however, to me so remarkable that, perhaps rashly, I have commented on the fact.

A relation of Negrito man to the "African" type of fauna seems possible, even if he were a very late development in this fauna, and he seems to have passed with it out of Europe and elsewhere, much as did some of the animals with which he is still associated. It is a fascinating but perhaps dangerous surmise to wonder whether man's early history was not a natural part of some at least of the great world faunas, and whether these may not represent in turn passing and oncoming geologico-faunal phases. But I must leave such considerations to those more competent to deal with them and pass on to the third of our trio of forms, the malaria parasite.

Of the malaria parasite there are known at present three, possibly five, distinct species. We are entitled to ask whether these shew any relation to the human or anopheline faunas. Modern conditions and the increasing extension and admixture of races under the conditions of civilisation must undoubtedly have tended very greatly to obscure any relationship to man and it is doubtful if as yet any definite relationship to species of *Anopheles* has been ever demonstrated. Nevertheless the present distribution of the species of parasite is at least suggestive. It might add some incentive to more extensive and accurate observations if it were realised that there might be some trace left of the faunal distribution of these forms. Latterly there has been some reason to believe that the parasite recently described by Stephens as *P. tenue* is very characteristic of the Central Indian area, an area largely populated by aboriginal races. Whether any recognisable relation of human parasites to faunas can be traced is perhaps doubtful, but the wider recognition by medical and veterinary workers of the truly amazing fact of the great world faunas is at least much to be desired.

By E. A. ANDREWS.

Mr. E. A. Andrews said: We have listened to three very interesting papers giving an account of the relationships known to exist between insects and man and animals, and plants, respectively, but I should like to strike a different note, and speak, not so much of the relations existing between insects and plants, for I speak, of course, from the agricultural side, as of the factors affecting those relationships.

The speakers on the medical and veterinary sides have stressed the pathological nature of the problem, but the study of the relationships between plants and insects raises many pathological problems too, and when we compare the number of cultivated plants with the number of domestic animals, I think that, while admitting Mr. Edwards' claim that the field for investigation is much wider on the veterinary side than on the medical, we can claim that the field on the agricultural side is wider still.

The object of this meeting being to promote discussion, I do not propose to do more than give a general account of observations made in connection with the study of the insect pests of the tea plant, which we believe to shed a certain small amount of light on this aspect of the question, with the hope of introducing this point of view to a proper notice in the discussion.

Let us consider the case of two very common insect pests in our part of India, the cabbage caterpillar and the looper caterpillar of tea. The vegetable garden may be planted immediately alongside the tea area, yet the former is never known to attack tea and the latter is never known to attack cabbages. Why?

In this particular instance it is possible to beg the question by pointing to the extreme dissimilarity between the plants and the difference in systematic position of the insects, but when it is found, as we have found in the case, more particularly, of the arch-enemy of tea, the tea mosquito bug, that not only varieties of the same species, but individuals of the same variety, may behave towards the tea mosquito bug as the cabbage does to the looper caterpillar, while their neighbours succumb to attack, it is impossible to ignore the existence of whatever factor it is which determines the choice which appears to be exercised by the insect.

In such cases it is obvious that the determining factor lies, not in the insect, but in the bush, and it is by enquiries into the factors governing this phenomenon that we have been able to carry out researches to such an extent as to cause tea bushes which were already closed down by the pest to throw it off completely and continue to give copious flushes, while their untreated neighbours rapidly succumbed.

In considering a problem of this nature the first thing we have to realise is that the question we are considering is neither the insect nor the bush, but the reactions between the two. This reaction is of necessity governed, not only by the peculiarities of the insect, but also by the peculiarities of the bush. As soon as we adopt this attitude towards the problem we realise that all factors affecting both the insect and the bush must be taken into consideration, and that it is impossible to omit from consideration the effect on both the insect and the bush, of the environment in which they are situated.

Our observations must therefore be extended to include an exhaustive enquiry into the conditions of the environment, and their possible effect on both the insect and the plant. In the case of an instance such as I have cited, where bushes in close contiguity show differences in degree of liability to attack, it is obvious that the effect of environmental conditions on the insect must be similar in the two cases, and we are compelled to a study of the environmental conditions as regards their effect on the bush.

Since time is limited, and there are many present to express opinions, I shall not dilate upon this aspect of the matter, but shall confine myself to a sketchy outline of the results we have obtained to show the direction in which work based on these conceptions has tended.

The environment of a plant is complex, and there are many environmental factors which have to be considered. Some of these are:—the geographical situation, the topographical situation, the elevation, the exposure of the place, the provision of shade, windbreaks, etc., and the soil in which the plants are situated. All the foregoing can be controlled at the time of planting and govern amongst other things, the variations in temperature, humidity and so on, to which the plant is exposed.

Having planted our bush, however, it is still subject to seasonal climatic fluctuations, but, what is more important, and especially in cases where intensive cultivation is the rule, it is subject to considerable variation in the condition of the soil environment.

Our work has therefore included an extensive survey of soil conditions as affecting the well-being of the bush and the incidence of the pest, and to cut a long story short, it was as a result of these investigations that we were led to the conclusion that a shortage of potash in the plant, as compared with phosphoric acid, was conducive to more severe attack. Carrying the work further, we were able, by direct addition of potash to the plant, to bring about the apparently complete immunity which I referred to before. This might lead one to suppose that the obvious thing to do is to add potash manures to the soil, and this was of course tried, with the result that, although a transitory improvement was effected by this means in most cases, it was found that there appear to be more factors than one affecting the power of the bush to obtain potash from the soil.

The work is now being carried further, and attempts are being made to investigate the minutiae of the reactions between the insect and the plant on the one hand and the plant and the soil on the other, as a result of which we have already obtained indications that the hydrogen ion concentration value of the soil solution, and again of the sap of the plant appears to enter into the matter, while the relative proportions of different substances in the sap does appear to vary from bush to bush, even when they are in close proximity.

In this direction the work appears to be running more or less parallel to much of the work which is being done in the medical and veterinary sections, and I hope I have said sufficient to excite interest in this side of the question as it affects the point of view of the agricultural investigator, for from the results obtained on these lines not only by us, but also by investigators in other parts of the world, it would appear

that the field for investigation is not only a very wide, but a very promising one.

By J. T. EDWARDS.

Mr. Edwards stated that the field under discussion had been covered briefly from the veterinary standpoint in the paper read by his colleague, Mr. S. K. Sen. There was not much difficulty after listening to what had been already said at the meeting, in perceiving a remarkable analogy in the role of insects as concerned human, animal, and plant pathology. The parts played by the insect factor in human pathology as disclosed in Colonel Mackie's address were exactly of the same order as those enumerated by Mr. Sen in his summary, with the difference that the animal pathologist was concerned with a considerably larger field, in view of the greater number of host subjects exposed to attack. Again, what had been stated by Colonel Christophers in his interesting speculative discussion upon the geographical distribution of association among human beings, mosquitoes, and the various species of malarial parasites could be applied with the same suggestive implications to the widespread interdependence of three other zoological species, namely, cattle, ticks, and various species of piroplasmas. Further, the role of minute defects in nutrition, through lack of adequate mineral substances in the soil, in depressing the capacity of resistance of the plant so as to render it susceptible to the attack of an insect parasite, as revealed in Mr. Andrews' illuminating contribution, had what seemed to be an instructive analogy in the cattle disease known in South Africa as *lamziekte*, a disease which also undoubtedly occurred in parts of India. Phosphatic deficiency in the soil, and hence in fodder grown upon enzootic areas, led to the establishment of abnormal craving in the cattle, which were thus addicted to consuming decomposing bones strewn upon the pastures infected with a powerful toxicogenic bacillus, probably often conveyed by blood flies to the carcasses. The Imperial Entomologist had endeavoured in his paper to furnish a monetary computation of the losses annually sustained by India from the depredations caused by insects parasites and although the losses caused among live-stock were held to be large, they represented but a small fraction of the total losses sustained by agricultural interests. The speaker nevertheless contended that the loss was much greater than could be fairly represented in such figures, for disease in cattle meant serious hindrance to the cultivator anywhere, irrespective of the nature of the crop grown, in much the same way as outbreaks of the fly-borne disease of horses and camels known as *surra* might result in the immobility of armies. Numerous examinations at Muktesar during recent years had indicated that cattle in India nearly everywhere harbour vector-transmitted parasites, but the exposure to this attack seemed to be of such long standing that they were locally largely immune (piroplasmas, trypanosomes). Disease directly due to insect attack (maggots or myiasis) caused widespread losses. It seemed that a clear case had been made for supporting the Imperial Entomologist's scheme for the centralisation and enlargement of the entomological resources of the country, and thus for the establishment of an organisation from which the investigator working upon pathological problems could seek trained entomological assistance.

By P. B. RICHARDS.

Mr. P. B. Richards said he had anticipated from the subject of the discussion that this would centre on insects as vectors of diseases of animals and plants. A broader line had, however, been taken by the agricultural contributors to the discussion which may be justified if they are permitted to consider insect-pest attack as, in itself, a disease, in which case pest insects in the aggregate might be said to be the worst disease from which plants suffer. This view was not so far-fetched as it might at first appear. The effect of disease

was to produce pathological conditions in the organism attacked. Insects certainly did this to the attacked plants. Analogies with animal pathology might, perhaps, be admitted between scale insects and skin diseases, insect-formed galls and tumours, mining and boring insects and myiasis. Sucking bugs in the course of piercing plants to abstract the juices broke down cells and vessels to a considerable degree. It was but one step further to the injuries inflicted by biting insects which removed plant organs in part or completely.

As instances of insects serving as vectors of specific diseases of plants, Mr. Richards cited the conveyance of fungus diseases into *Hevea brasiliensis* by the timber-nesting white ant, *Termes gestroi*, and by shot-hole borers, in Malaya; bud-rot into coconut-palms by *Oryctes rhinoceros*; and the probable relation between mosaic disease of potatoes in India and small sucking bugs.

The Imperial Entomologist in his paper had estimated the loss to agricultural crops at 10 per cent. This aggregated to an enormous sum, but Mr. Richards thought it might easily prove an under-estimate even of direct damage. For example in the United Provinces the loss of cotton crop on account of pink boll-worm attack alone appeared to be over 25 per cent., representing a loss of two and a half crores of rupees a year.

He feared there must inevitably be a certain toll taken by insects upon agriculture. The rate of toll would vary for different climates, crops, and peoples. Below a certain percentage loss for each set of conditions, remedial treatment would be uneconomic. But where the percentage loss is high, as in cotton, rice, stored potatoes, stored grain; or when a product of high commercial value is attacked, as tea; or individual plants of considerable value are injured, as coconut-palms by beetles, control measures were strongly to be recommended. He felt, however, that at present in India a great deal of the loss was unpreventable and that generally it was not a sound economic proposition to treat field crops under the present conditions of Indian agriculture. Methods of control for pest-insect pests had been evolved, but even where they were sound economically their application was limited by the ignorance of natural history, by the prejudice and, not least, by the poverty of the cultivator.

Hope might perhaps spring from the idea arising out of Mr. Andrews' work on tea, and from Mr. and Mrs. Howards' investigations at Pusa, that insect attack may prove to be a concomitant of ill-health due to some deficiency in the plant or unsuitability in its environment. The control of insect damage would then resolve itself in the future into growing "healthy" plants.

By A. HOWARD.

Mr. A. Howard said: During the last twenty years I have often observed the extraordinary degree of resistance to insect attack exhibited by plants when the right variety is cultivated and when suitable methods of agriculture are employed. On the other hand, unsuitable varieties and improper treatment are frequently followed by an epidemic. A collection of varieties of the same crop obtained from various tracts often contains types which differ greatly in immunity and susceptibility to disease. These differences are sometimes associated with the relation between the root-system and the soil-type. An interesting example occurred at Pusa in 1921, when certain deep-rooted varieties of a pulse, known locally as *Khesari* (*Lathyrus sativus* L.), were attacked by green-fly. In that year, deep-rooted varieties from the black soils, shallow-rooted types from the alluvium, as well as kinds with an intermediate root-system from the Allahabad District, were sown in the same plot. All the types from the black soil area were badly attacked by green-fly, all those from the alluvium were immune, while the types with intermediate root-development were only slightly affected. Although the infected and disease-free plots were often side by side, in no case did the *Aphides* leave the deep-rooted cultures and attack those with shallow

roots. Really healthy plants seem able to keep insects and fungi at bay and their juices seem unsuitable for the nourishment of these organisms. It is sometimes possible to alter the juices of a plant very rapidly by suitable treatment of the soil and to bring about great changes in resistance to insect attack. Thus at Quetta in the case of the almond and the peach, heavy winter irrigation was found to render these plants exceedingly susceptible to the attacks of green-fly, while normally grown trees side by side were practically immune. Deep cultivation and thorough soil aeration after the green-fly attack developed, were followed by greatly increased resistance to the disease. The first-formed leaves on these trees showed extensive damage by the pest, the late-formed foliage on the same trees was normal and perfectly healthy. The disease never spread from the old to the new leaves. These examples, of which many others could be quoted, suggest that the attacks of parasites only follow mistakes in the choice of varieties and in agricultural treatment. The experience of the sugar planters in Java certainly falls in with this view, which, if established by more examples, will lead to parasites being regarded not as pests to be destroyed but as very valuable indicators provided by Nature, for checking the proceedings of the agriculturist. The appearance of a pest in agriculture may merely show (1) that the wrong variety is being grown; (2) that the crop is being grown in the wrong way; or (3) that Nature did not intend it to be grown at all.

The discussion was continued by other members throughout the day's session and was of much interest.

The President concluded the meeting by expressing his thanks to those members of his and other sections who had so kindly contributed to the discussion. He added that he was sure they would all agree that a most interesting and instructive meeting had been held, and speaking for himself he could say that his outlook on the whole subject had been widened. It was interesting to see how similar the problem was which each branch of science had to face and particularly how much of value was contributed to the problem by agriculturists who had relatively simple problems to face. One truth which emerged was that the "Soil" was at least as important as the "seed" and this applied to human problems as much as to those of animals and plants. If men, animals, and plants were well fed and lived an hygienic life, they were much less liable to the ravages of insect-borne disease or to those caused by bacteria than those whose constitution had been undermined by unhealthy conditions of life. That, in a nut-shell, is the modern outlook on the problems of disease transmission.

"Medical Discovery."

A few extracts are given from a stimulating address by Sir Ronald Ross on "Medical Discovery." This was printed in full in *Science Progress* for January, 1925.

"What strikes us most in the picture are first the amazing extent and yet the slowness of the advance; and secondly, its intermittent or, rather, its undulant course. How many centuries have elapsed since our ancestral species first descended from the trees and took to hunting on the hard ground, not even the palæontologists can tell us with certainty: evolution itself is a part of discovery, unconscious or conscious. After that, weapons, habitations, and clothing were, we may opine, the earliest discoveries; and then came crops and herds, fire, boats, and wheeled vehicles, the

use of animals for draught or riding, fortifications, villages and cities, and social ordinances. We are not disposed to contemplate with pleasure or pride the earliest members of our own profession, the 'medicine men' of savage tribes; but nevertheless they must have been not only the first physicians but also probably the first priests and philosophers.

"Our knowledge of ancient Egyptian, Sumerian, Indian, and Chinese medicine is very small; but advances in all these countries were apparently periodic, though, I fancy, they were probably much greater than we can now judge from the very few inscriptions or books on medical subjects which survive. For example, the great Indian medical works were compiled within the second to the seventh century A.D., and showed considerable knowledge. It is not true that—as has been claimed—Susruta (fifth century) attributed malarial fever to mosquitoes; but these books indicate some discrimination of many diseases, including diabetes and also the use of many drugs; and they describe a hundred and twenty-one surgical instruments, many of which 'were properly handled and jointed, the blade instruments sharp enough to cut a hair and kept clean by wrapping in flannel in a box'—to quote from Dr. Fielding H. Garrison's admirable 'History of Medicine' (Saunders, 1917).

"This was, of course, after the great period of Greek and Alexandrian sciences, from which much of the Indian medical learning (like Indian mathematics) was quite possibly derived—though Indian physicians and surgeons were well recognised as early as the time of Alexander. Both the Greeks and the Indians seemed to know that rats are connected with plague. The Greeks certainly connected malaria with marshy soil, and were able to distinguish the tertian, subtertian and quartan varieties; and Empedocles of Agrigento in Sicily was said to have cleared that town of malaria by removing its marshes as early as the fifth century B.C. (I suspect that the reason why he threw himself into the crater of Etna was because of his disgust at the indifference of his countrymen towards anti-malaria measures). I need scarcely discuss Hippocrates (460-370 B.C.) here, but may repeat the old complaint that ancient medicine went very slowly after his time. Nevertheless there was some considerable advance after him and with the Alexandrian anatomists to Galen (A.D. 131-201), whom also I need not particularise. The whole period lasted about seven hundred years, and then the sun of medical science set for nearly thirteen centuries, except for those faint reflections of its ancient glory which still haunted that long night. Now observe another fact. The entire epoch of Graeco-Roman medicine produced only a few men who added materially to medical science. The excellent chapter of Dr. Garrison's work, for example, which deals with this epoch, contains only eighteen black-letter names, including Hippocrates and Galen, in the whole seven centuries.

The revival of learning, or rather of discovery, commenced in the fifteenth and sixteenth centuries, nearly thirteen centuries after the death of Galen; and was at first largely concerned with refutations of that somewhat imaginative writer. The original observations of the new era began with those of the great Italian anatomists, Vesalius, Eustachius, Fallopius, and Fabricius, who re-constructed the science in the sixteenth century. Harvey published his demonstration of the circulation of the blood in 1628; and the microscope, the telescope of biology and medicine, began to be used by Kircher, Hooke, Swammerdam, van Leeuwenhoek, and Malpighi shortly afterwards. In the latter half of the same century (the seventeenth) Redi disproved 'spontaneous generation.' Towards the end of the eighteenth century Jenner's great discovery of vaccination opened up the study of immunity against disease; and in the nineteenth century Lister, Pasteur and Koch created bacteriology; Kuchemister, Leuckart, and Laveran developed parasitology; and rapid advances were made in every branch of medicine. In

Dr. Garrison's book the names of the men who made the leading advances in medicine are entered in black letters, and on counting them we obtain the following results:—During the century and a half from A.D. 1450 to 1600 there are 46 names; during the seventeenth century there are 79 names; during the eighteenth century 122 names; and during the nineteenth, 446 names. There are altogether nearly 700 names in the four and a half centuries from 1450 to 1900. During the same period many thousands of millions of human beings have lived and died throughout the world; and yet only about seven hundred of them altogether have added materially to medical knowledge. Secondly, nearly all of these seven hundred lived in the comparatively small proportion of the world's surface included within Italy, France, Britain, Holland, Belgium, Scandinavia and Germany. Thirdly, these men were only a small proportion even of all the medical practitioners who had lived during the same period—there are more than thirty thousand medical practitioners in Great Britain to-day; but fourthly, many of the most important advances (such as those of Jenner, Lister, Koch and Laveran) were made by men who were 'private practitioners' at the time.

"The proportion of medical discoverers in Dr. Garrison's list to the total population of the world is probably nearer to one in ten million than to one in a million as previously conjectured in this paper; and the proportion of them to all medical men is probably something like one in a thousand. But this gives rather a false estimate of the real work which is being done in medicine—to-day at least. If we count only the generals of an army, that army will be but a small one. Actually an immense amount of work is being turned out daily by the rank and file, though medical history can take cognisance only of the leaders; and we have but to read our copious contemporary medical press to convince ourselves of this fact. A very large proportion of the medical profession of to-day add something, however small, to the store—contribute their mite to the mass of knowledge, lay a brick or two to build the magnificent palace of science. We are apt to overlook this constant but almost inappreciable accretion. There are no strikes in the building trade of science. Day after day, year after year, the structure grows before our eyes. The men whose names appear in the medical anthologies are those who dug the foundations, or perhaps those who have completed the towers and the pinnacles; but it is the thousands engaged in treating the sick who have actually raised the walls of that august temple.

"I remember that before the war several of our colonies laid it down among the duties of their medical officers that they should 'engage in research.' What an easy rule to make! The popular notion is that a man has only to glance through a microscope in order to find something new. A friend of mine once said that the world looks upon any doctor as a person who, on returning home after a hard day's work, pulls out his watch and exclaims, 'Ah! I have half an hour to spare before dinner. I will just step down to my laboratory and make a discovery.' As a matter of fact it is impossible for most busy practitioners to indulge in such a time-wasting and often fruitless or nerve-wracking pursuit as deliberate, meticulous, and exigent investigation. What many of them really do, however, is to collect an enormous mass of observations on the symptomatology, the pathology and the treatment of diseases; and it is on this basis that the most important advances are made by subsequent diligent laboratory work or brain work. After all, the brain is the best by itself, is not enough: we have to co-ordinate observations. The ultimate object of science is not merely to make and to record observations, but to classify them in groups, and then to show that one group of them depends upon another group—that is, to solve problems. For example, many surgeons had studied, described and despaired over septic wounds; but it was Lister who

discovered how septic wounds were caused and could be prevented. Long before Jenner, milkmaids and farmhands believed that if they acquired cowpox they would not acquire smallpox; but it was Edward Jenner who co-ordinated such statements, tested them experimentally and created vaccination. Science requires not only observation but proof, and not only proof but explanation. Now, it is one thing to make observations, but quite another thing—and usually a much more laborious process—to verify them and to explain them.

"To put it briefly, medical discovery is to us human beings even the most important of all kinds of discovery, as defined in this paper. Yet to judge from the public attention given to it, it is the least important. Men seem to pass it over as if it were of no consequence; they hand it over in mass to the 'doctors'; and they are good enough to subscribe almost no money to the prosecution of it. The total fund now allotted for medical research in Britain consists of about £130,000 a year given to the Medical Research Council; and something like (I cannot ascertain exactly) the sum of another £50,000 a year for pure medical research, as distinct from teaching, provides for the numerous research laboratories and institutions. The total would amount to about £180,000 a year, if I am not far wrong. What a gigantic sum this is—what a generous contribution from this wealthy State to the science which is concerned with the life and health of all the people! Think of it; £180,000 a year! That is to say, one penny per annum given by each living person in Scotland, England and Wales. What generosity! For this gigantic penny every one hopes to have his life prolonged to at least the maximum of the three score years and ten laid down by the Psalmist. Think of it again; during seventy years each person will have given seventy pennies, that is a total of 5s. 10d. for this cause. In the meantime every such person will have given many pounds to pay for his politicians, his army and navy, his local municipal affairs, and his education.

"The truth is that the mass of the people do not in the least even yet recognise the effect of medical discovery. I see from the Annual Report of the Medical Officer of Health for the County of London for 1923 that in 1841 the average expectation of life for every individual in London was 34.6 years among males and 38.3 years among females; and, that this period was prolonged last year to 53.8 years among males and 59.1 years among females. This means that the average length of life has now been prolonged by twenty years, that is by more than half of what the average length of life used to be in 1840. Of course, many factors have been concerned in this wonderful addition to life, but I think that one of the most potent factors has been the general increase of medical knowledge during that period of eighty-three years. Now perhaps if this fact can be violently rammed into the thick head of the general public, it might produce some effect upon the tightly drawn purse-strings of the same. If the public some day acquires sufficient sense, it will largely increase its contribution for medical science. I think that we doctors could easily arrange to spend on medical research a sum of not only £200,000 a year as at present, but of quite £1,000,000 a year; and what is more, the general public would really benefit by the expenditure—which is probably not the case if the public expenditure were to be correspondingly increased in many other lines, such as politics or even education.

"It is true, I think, that medical discovery does not require the supreme intellectual ability which is needed for astronomy, physics and mathematics. Archimedes, Descartes, Newton, Laplace, Clerk-Maxwell, Kelvin and the modern relativists possessed or possess, I believe, a more intense intellectual fire than the moderate heat needed for medical, and indeed for any biological studies. The reason for this is that, at least up to the present, biology requires observation rather than calculation—it has more to do with the collection of facts than with exact measurements and induced predictions. But it is a mistake to suppose, as is often done, that

any one and every one can equally and easily achieve biological and medical discovery. True, many important medical discoveries seem to have been made simply by good luck; but we are apt to forget the earlier years of toil and disappointment which generally preceded, and were only finally crowned by that good luck. Now any one can have good luck or bad luck; but not everyone is willing to face the previous years of effort. Medical discovery, like all discovery, requires two rather rare qualities—an acute instinct for the right direction, and a burning perseverance in following it up. Now in my opinion these qualities are possessed only by a few individuals; and—what is more—it is impossible to know whether any individual really possesses them until he has actually succeeded in his quest. We cannot isolate and detect the future discoverer by any known qualities—by his success in examinations, by the height of his brow, or by the cut of his collars. For these reasons I have always argued that the best way to encourage discoveries in the future is to keep at work, by whatever means you can, the few men who have actually achieved discoveries in the past; and this is by no means always done, at least in Britain, at present.

"Those who rule us never seem to gather wisdom in this respect. They like to leave all such investigations to be carried out by doctors at their own expense. For example, the solution of the malaria problem cost the Indian Government a sum of no less than £240 in the years 1898-99; and all the recent advances in tropical medicine—advances which were probably greater than those in any other branch of medicine in the same period—cost the world's governments somewhat similar sums. We doctors and other men of science may congratulate ourselves on one point, namely, that almost the whole of medical discovery has been made by ourselves without help from anyone and at our own expense. Let us boast about it and blow our own trumpets—because no one seems willing to do so for us, and much less to pay us for our work! The cancer problem is being cleared of many of its surrounding difficulties, but it still remains impregnable. Advance is not as quick in many lines where we expected triumphant issues years ago. For example hookworm disease can be easily cured in the patient but by no means so easily in the community. Though Leishman and Donovan found the cause of kala-azar twenty years ago we have failed to ascertain how it is carried; and I could spend an hour in discussing the victories which we have failed to make, just as I have already spent an hour in discussing some of those which we have made."

A Conversazione at Parel Laboratory.

THERE was a large and distinguished gathering at a conversazione held at the Bombay Bacteriological Laboratory, Parel, on February 20th, 1925, under the auspices of the Grant Medical College Society and the Bombay branch of the British Medical Association. His Excellency Sir Leslie Wilson was the principal guest of the evening, and Major-General A. Hooton and Sir Temulji B. Nariman and others were present.

The following is the text of Colonel Mackie's address, as Director of the Laboratory:—

Your Excellency, ladies and gentlemen,

I wish to place before you a short account of the work which has been carried on during the last year at this Laboratory.

(I) The preparation of plague prophylactic is, perhaps, the most important of our duties, and the output during 1924 has been nearly 15 lakhs or one and a half million doses. Only twice in the history of the Laboratory has this number been exceeded. A charge of two annas a dose is made to Government agencies and native States, and four annas a dose to foreign countries; and it is estimated that during this year

Rs. 2,20,000 will be recovered by the Bombay Government under this head. This pays nearly two-thirds of the whole cost of staffing and running the Laboratory.

The vaccine besides being supplied to all parts of India is also sent to Iraq, British East Africa, China and the Persian Gulf.

From the opening of the Laboratory in 1896 till now nearly 25 million doses have been issued. From carefully collected statistics it appears that the reduction in mortality by prophylactic injection of Haffkine's vaccine is about 47 per cent. That is to say if 100 people contract plague, 85 of them will die if they have not previously been inoculated; whereas only 38 will die if they have been previously protected by Haffkine's vaccine. In addition to this, fewer persons will contract plague amongst those inoculated than amongst those not inoculated. On this calculation several millions of lives have been saved by the use of this vaccine—surely a splendid monument to the memory of Professor Haffkine and of the laboratory he established. Laboratories have been named after other great benefactors of mankind, for instance the Pasteur Institutes in Paris and elsewhere, the Lister Institute in London, so that there are good reasons for styling this "The Haffkine Institute" which should remind India of one of its greatest benefactors.

(II) *Diagnosis of plague in rats.*—The Laboratory is used by the municipal authorities for the diagnosis of plague in rats trapped or found dead. By this means the presence of a rat epizootic and the approaching rise of human infection may be forecast. During the year 700,000 rats were received of which nearly 250,000 were alive and 450,000 were dead; 326,291 were dissected and 3,774 were found to be plague-infected, i.e., 1.16 per cent. The number of infected rats is low in January but rises rapidly in February, March and April, when it may then reach as high a percentage as 7 or 8, and it then falls rapidly to 1 or 2 per cent. with the advent of the hot weather. This interesting phenomenon is not due to any appreciable changes in the rats, but is the result of the play of physical forces such as temperature and humidity acting on the rat-flea population.

(III) *Diagnostic examinations* for the information of civil surgeons, private practitioners and others are carried out in large numbers at the Laboratory. These examinations are in the capable hands of Assistant Surgeon Khan Bahadur Avari. A total of 2,065 such examinations were carried out by this department last year, of which 1,386 were for the serological diagnosis of syphilis. In addition to this, 240 tumours were reported on and the necessary guide to their operative procedures was in this way given to surgeons.

(IV) *The Chemical Department* is concerned chiefly in the bacteriological and chemical analysis of waters, of sewage effluents and other manufacturing processes, and in addition valuable research work was done by Dr. Goré on intestinal bacteria and on other problems of a like nature.

(V) *The snake venom work* is carried on continuously and may be regarded in part as the advertising department of the Laboratory in that it provides a *tamasha* which is witnessed by many distinguished persons who pass through Bombay. The venom so obtained is used for the production of antivenene which is prepared at Kasauli and used all over India; whilst laboratories in various parts of the world apply to us for their requirements of this valuable and dangerously-won commodity.

(VI) In addition to these activities, the Laboratory takes some part in *educational and propaganda work*, especially in connection with the epidemiology of plague, malaria, fly-borne diseases, tuberculosis, milk supplies, guinea-worm disease, rabies and disease-carrying insects. You may have noted, Sir, the exhibits which we sent to the recent Baby Week Exhibition, and similar assistance is given to exhibitions in other cities in India.

The preparation of lantern slides and cinema films fully occupies the time of the artist-photographer and his assistant, and these are loaned all over India for educational purposes. Medical men are sent by other governments and native states for short courses of instruction in subjects in which we have special experience and facilities. This educational and propaganda work is increasing rapidly and may be looked upon as one of the most valuable activities of the Laboratory.

Having reviewed briefly what we may call the routine work of the Laboratory, we turn to the special units; namely, the anti-rabic, the pharmacological, and the biochemical, the first named of which is a healthy infant of two years, whilst the two latter have come into being this year.

(VII) *The Anti-rabic Unit.*—Major Morison held charge of this unit until he went on leave on 14th April, 1924. We were able then to obtain the services of Assistant Surgeon La Frenais, who in addition to large experience of Pasteur Institute work has done valuable research work on this subject.

The advantages of decentralisation of anti-rabic treatment are many and are fully appreciated by the public who are spared long journeys by rail to Kasauli, and, what is still more important, are able to come under very early treatment which is so important a factor in reducing the mortality from this dreadful disease.

A total of 1,099 persons came for treatment and of these 108 did not complete the full course.

The number of persons who went through the course (580) is less by 265 than those of the year 1923, and this is due to the broadcasting of the vaccine to new treatment-centres which were opened during the year. Thus in 1923, 1,396 treatments were issued, whilst during 1924 2,811 were issued. This represents a 100 per cent. increase. The cost of a complete treatment of 14 daily doses has been recently reduced to Rs. 10.

There are now 24 treatment-centres to which patients may resort, thirteen of which are under the Government of Bombay and 11 of which are either under military or railway authorities or in native states.

The brains of 185 dogs suspected of having died of rabies, were examined microscopically, and of these 99, i.e., just over half were found positive to rabies.

Now that the anti-rabic unit is fully established and has proved its usefulness, it is highly desirable that house accommodation be provided on the premises for the officer in charge, Assistant Surgeon La Frenais.

(VIII) *The Pharmacological Unit.*—The department for the study of indigenous drugs was established during the year. The Revd. Father Caius, S.J., was appointed to the charge of the unit and entered on his duties as Chemist on 1st June, 1924. The pay of Father Caius was generously provided for the first year by the Governing Body of the Indian Research Fund Association and the working expenses of the unit have been guaranteed for two years by Your Excellency's Government.

Dr. Mhaskar, an Assistant Director of the Laboratory, was appointed to replace Dr. Turkhud and took over his work in association with Father Caius in the new unit on 14th June, 1924.

These two officers have already done some interesting work on the therapeutic value of indigenous drugs, viz., *Holarhena antidysenterica*, *Butea frondosa*, *Gymnema sylvestre*, and *Kino*. The first named appears to be a valuable remedy in certain forms of dysentery and diarrhoea and the second yields a substance toxic to *Ascaris* worm infection. Papers on these subjects were submitted to the recent Indian Science Congress at Benares, but are too technical to be referred to further on this occasion. Father Caius and Dr. Mhaskar are present in their laboratories to-day, and will be glad to show their methods and results to any medical men who care to pay them a visit.

(IX) *The Biochemical Unit.*—This laboratory has only just been opened (on December 15th, 1924), and the
